Abstract

We present a Fortran 77/95 code capable of computing QCD corrections in deep inelastic scattering (DIS). The code uses the Projection-to-Born method to augment an existing $\mathcal{O}(\alpha_s^2)$ dijet DIS code, thereby obtaining predictions for photon-mediated neutral-current single-jet DIS production in the laboratory frame. The code is lightweight and fast, and yet includes the most common functionalities found in typical perturbative QCD programs, like automatic renormalisation and factorisation scale uncertainties, options to run and combine multiple seeds, and interfaces to fastjet and LHAPDF. Due to the underlying `disent` and `HOPPET` codes, the program also provides stable results in the infrared, relevant for extracting logarithmic coefficients for analytic resummations, and access to the massless DIS structure functions and (reduced) cross sections up to $\mathcal{O}(\alpha_s^3)$.

1 Introduction

Deep inelastic scattering (DIS) is arguably one of the best understood processes in perturbative QCD. It is one of few processes for which there exists an exact factorisation theorem [1, 2], and the massless unpolarised hard perturbative coefficients have been computed through an impressive three loops [3–15] with progress on the four loop results presented recently in Ref. [16]. Together with the three-loop results for the DGLAP splitting functions [17–19] and the four-loop β -function [20, 21] for the running coupling this allows for the determination of the massless proton structure functions at the next-to-next-to-next-to-leading order (N^3 LO).¹ The structure functions can be combined with an exclusive next-to-next-to-leading order (NNLO) dijet DIS computation to obtain fully differential N^3 LO predictions for single-jet DIS production, as was done by the NNLOJET collaboration [39–41]. This computation uses the Projection-to-Born (P2B) method, which was first introduced in the context of NNLO Vector Boson Fusion (VBF) production [42], and has since also been extended to N^3 LO colour-singlet production in proton-proton collisions [43, 44].

Despite this impressive theoretical progress, there are few publically available computer codes from which one can obtain fast and reliable high-order differential cross section predictions for DIS. This paper and associated Fortran code seeks to address that.

One of the advantages of the P2B method is that it is rather agnostic towards the details of the underlying exclusive computation, and it is hence possible to augment the validity of existing fixed-order codes. Historically the most successful fixed-order codes have been MEPJET [45], `disent` [46], `disaster++` [47], and `nlojet++` [48] which are all next-to-leading order (NLO) accurate for DIS dijet production. Discrepancies between `disent` and fixed-order coefficients from analytical resummation were initially observed in Refs. [49, 50], and were only recently understood to be due to a bug in one of the dipole terms for the gluon channel in `disent` [51, 52].

With the bug fixed we can use `disent` as the underlying exclusive dijet NLO code together with the NNLO structure functions from HOPPET [53, 54],² to obtain fully differential single-jet DIS predictions. Advantages of using `disent` are its well-known efficiency and numerical stability. The resulting program is dubbed `disorder` keeping in the spirit of previous names for fixed-order DIS codes.³ Since the program relies on HOPPET for the structure functions, the inclusive DIS cross section can actually be obtained one order higher, as the structure functions were implemented at N^3 LO already in the context of the `proVBFH` codes [42, 57–59] and are

¹Technically the four-loop splitting functions are needed to claim this accuracy. Recent progress in determining those and the three-loop massive operator matrix elements, needed for the variable-flavour-number scheme [22], can be found in Refs. [23–30] and [31–38] respectively. Phenomenologically the first few moments which have been computed therein, with some exact pieces also being known, are however in all likelihood enough to claim N^3 LO.

²The combination of `disent` and HOPPET naturally leads to a Fortran code. For a C++ alternative, based on publically available codes, one could have started from either `disaster++` or `nlojet++` and used the structure functions as implemented in APFEL++ [55, 56].

³`dispatch` [50] deserves an honorable mentioning in this context.

publically available since v1.3.0 of HOPPET [60].⁴ The `disorder` program therefore has two more or less separate use cases: 1. The computation of fully differential $\mathcal{O}(\alpha_s^2)$ photon-mediated neutral-current (NC) massless DIS and 2. The computation of inclusive and charged-current (CC) massless DIS at N³LO accuracy.

DIS is peculiar in-so-far that despite having a final-state parton already at the lowest order, the existence of a non-trivial jet, at this order, is highly frame-dependent. The majority of jet analyses are performed in the Breit-frame, as was for instance the case at HERA [61–68]. In this frame the incoming proton collides head-on with the photon, and the resulting jet has zero transverse momentum. At NLO, the real-emission diagram can instead give rise to two jets with equal and opposite transverse momentum, provided the two partons are not clustered together. As a consequence, the first non-trivial jet process that can be described in the Breit-frame is dijet production. In contrast, in the laboratory frame (or virtually any other frame than the Breit-frame) there will always be at least one jet present.⁵ The P2B method therefore only meaningfully augments the `disent` program in the laboratory frame, where single-jet production is well-defined. Hence, when analysing the output of `disorder` in the Breit-frame it will essentially be identical to that which one would obtain by running a stand-alone version of `disent`, with the addition that the inclusive NNLO cross section is computed correctly at the same time.

The `disorder` program is designed to be user-friendly with a simple command line interface. It prints cross sections and all important run-parameters to the screen and disk, allowing a user to acquire cross sections with very little effort. It comes with an interface to `fastjet` [76] and LHAPDF [77] and uses the histogramming package from the POWHEG-BOX [78] for easy analysis. The code can also compute renormalisation and factorisation scale uncertainties on-the-fly. For inclusive cross sections the code provides results in a matter of seconds⁶ even at N³LO with integration uncertainties typically below the permille level. For exclusive quantities the code can be run on a laptop at NLO and depending on the analysis, and the laptop, even at NNLO.

It should be pointed out that the code provides little theoretical advance on its own. As described above, the structure functions themselves have been known for a while, and the P2B method has already been applied to DIS, even one order higher than here.⁷ In addition only photon-mediated DIS can be computed fully differentially at the moment. It is however the author’s opinion that with the renewed interest in DIS due to the upcoming Electron-Ion-Collider (EIC) [82], well-maintained public code is extremely valuable for both the experimental and theoretical communities, and that providing documentation in the form of this article will enable the wide use of the code.

The paper is structured as follows: In section 2 we review the DIS process and kinematics as implemented in `disorder`. In section 3 we provide details on how to run `disorder` and in section 4 we show a few results from the program. Finally we conclude in section 5.

2 Basics of the DIS process

In this section we first give some standard definitions for kinematics and cross sections in DIS. Along the way we specify the conventions that are used in the `disorder` code, and provide some details on the P2B method as applied there.

⁴HOPPET implements all known approximate and exact ingredients at this order - see footnote 1.

⁵Although the Breit-frame is used in most analyses, there exist many laboratory frame measurements as well [69–74] including the very recent ZEUS measurement [75].

⁶The majority of this time is taken up by the structure function initialisation inside HOPPET rather than the integration of the cross section.

⁷It has also been applied in polarised DIS in Refs. [51, 52, 79–81].

At leading order (LO) the DIS process is the scattering of a massless (anti-)quark q off a massless (anti-)lepton l via the exchange of a photon or electroweak gauge boson V of virtuality Q^2 . Denoting the external four-momenta by k_i (incoming lepton), k_f (outgoing lepton), p_i (incoming quark), and p_f (outgoing quark) we can define the Lorentz invariant DIS variables x , Q^2 , and y , given by

$$Q^2 = -q^2 = -(k_i - k_f)^2, \quad x = \frac{Q^2}{2P \cdot q}, \quad y = \frac{P \cdot q}{P \cdot k_i} = \frac{p_i \cdot q}{p_i \cdot k_i}, \quad (1)$$

where P is the hadron four-momentum. As can be seen these kinematics are fully specified by the hadron and lepton momenta. This is also true beyond LO.

DIS is most often analysed in the Breit-frame which is specified by requiring that $2x\vec{P} + \vec{q} = 0$.⁸ In this frame the mediated vector boson has zero energy component and is anti-aligned with the incoming parton. Explicitly in disorder the Breit-frame at LO is

$$\begin{aligned} k_i &= \frac{Q}{2} \left(\frac{2-y}{y}, \frac{2\sqrt{1-y}}{y}, 0, -1 \right), & p_i &= \frac{Q}{2} (1, 0, 0, +1), \\ k_f &= \frac{Q}{2} \left(\frac{2-y}{y}, \frac{2\sqrt{1-y}}{y}, 0, +1 \right), & p_f &= \frac{Q}{2} (1, 0, 0, -1), \end{aligned} \quad (2)$$

where four-momenta are given as (E, p_x, p_y, p_z) . The resulting vector q is hence given by $(0, 0, 0, -Q)$. It is clear from eq. (2) that the outgoing parton in the Breit-frame has zero transverse momentum. In the laboratory frame we align the parton with the positive z -axis and hence the lepton with the negative

$$\tilde{k}_i = E_l (1, 0, 0, -1), \quad \tilde{p}_i = xE_h (1, 0, 0, +1), \quad (3)$$

where E_h is the energy of the incoming hadron. Using the definitions of eq. (1) one finds that in the lab frame

$$\tilde{q} = (y(E_l - xE_h), -Q\sqrt{1-y}, 0, -y(E_l - xE_h)), \quad (4)$$

and the outgoing momenta then simply follow from momentum conservation

$$\tilde{k}_f = \tilde{k}_i - \tilde{q}, \quad \tilde{p}_f = \tilde{p}_i + \tilde{q}. \quad (5)$$

Conversely, in the laboratory frame, the outgoing parton always has transverse momentum of magnitude $Q\sqrt{1-y}$. In disorder both the Breit-frame and laboratory frame momenta can be accessed by the analysis at the same time.

The inclusive cross section for DIS can be split into a NC contribution, from $e^\pm p \rightarrow e^\pm + X$ scattering, and a CC contribution from $e^\pm p \rightarrow \nu + X$ scattering.⁹ The unpolarised NC cross section can be written as

$$\frac{d\sigma_{\text{NC}}^\pm}{dx dQ^2} = \frac{2\pi\alpha^2}{xQ^4} [y_+ F_2^{\text{NC}} \mp y_- x F_3^{\text{NC}} - y^2 F_L^{\text{NC}}], \quad (6)$$

where $y_\pm = 1 \pm (1-y)^2$, α is the fine structure constant and F_i^{NC} can be expressed in terms of the usual proton structure functions

$$\begin{aligned} F_i^{\text{NC}} &= F_i^\gamma - v_e \Gamma_{\gamma Z} F_i^{\gamma Z} + (v_e^2 + a_e^2) \Gamma_Z F_i^Z, \quad i = 2, L, \\ F_3^{\text{NC}} &= -a_e \Gamma_{\gamma Z} F_3^{\gamma Z} + 2v_e a_e \Gamma_Z F_3^Z. \end{aligned} \quad (7)$$

⁸For the explicit transformation between lab- and Breit-frames we follow Appendix 7.11 in Ref. [83].

⁹Here $\nu = \{v_e, \bar{v}_e\}$ for e^- and e^+ respectively. One can of course also consider incoming neutrinos which does not change the discussion here, except adding a factor 2 in eq. (9) and changing the vector and axial-vector couplings to $v_e = \frac{1}{2}$ and $a_e = -\frac{1}{2}$.

Here $v_e = -\frac{1}{2} + 2 \sin^2 \theta_W$ and $a_e = \frac{1}{2}$ are the vector and axial-vector couplings respectively, M_Z is the Z boson mass, $\Gamma_{\gamma Z} = \frac{Q^2}{\sin^2 2\theta_W(Q^2 + M_Z^2)}$, and $\Gamma_Z = \Gamma_{\gamma Z}^2$. θ_W is the weak mixing angle. In `disorder` the electroweak parameters are fixed by α , M_W , and M_Z through the tree-level relations

$$\sin^2 \theta_W = 1 - \frac{M_W^2}{M_Z^2}, \quad G_F = \frac{\pi\alpha}{\sqrt{2}M_W^2 \sin^2 \theta_W}, \quad (8)$$

with G_F the Fermi constant. Similarly we define the unpolarised CC cross section as

$$\frac{d\sigma_{\text{CC}}^{\pm}}{dx dQ^2} = \frac{2\pi\alpha^2}{xQ^4} \left[\frac{Q^2}{4\sin^2 \theta_W(M_W^2 + Q^2)} \right]^2 [y_+ F_2^{\text{CC}} \mp y_- x F_3^{\text{CC}} - y^2 F_L^{\text{CC}}], \quad (9)$$

where M_W is the mass of W boson and the CC structure functions are now simply given by the W ones

$$F_2^{\text{CC}} = F_2^{W^\pm}, \quad F_L^{\text{CC}} = F_L^{W^\pm}, \quad F_3^{\text{CC}} = F_3^{W^\pm}. \quad (10)$$

The exact definitions of all proton structure functions inside `HOPPET` up to N³LO can be found in Refs. [53, 54, 60]. The tabulation of the structure functions inside `HOPPET`, as used in `disorder`, has a relative numerical precision of 10⁻⁴ for most values of x , which in turn limits the accuracy which can be obtained to the same order.

In DIS it is also customary to define the dimensionless *reduced* NC and CC cross sections by [84]

$$\begin{aligned} \tilde{\sigma}_{\text{NC}}^{\pm}(x, Q^2) &= \frac{xQ^4}{2\pi\alpha^2} \frac{1}{y_+} \frac{d\sigma_{\text{NC}}^{\pm}}{dx dQ^2}, \\ \tilde{\sigma}_{\text{CC}}^{\pm}(x, Q^2) &= \frac{8\sin^4 \theta_W x}{\pi\alpha^2} [M_W^2 + Q^2]^2 \frac{d\sigma_{\text{CC}}^{\pm}}{dx dQ^2}. \end{aligned} \quad (11)$$

`disorder` provides direct access to all the cross sections in eqs. (6), (9), and (11) at N³LO accuracy. In principle one can also access the NC and CC structure functions, although they are currently only computed as an intermediate step to construct the cross sections and are not accessible in the user analysis.

2.1 A note on the phase space

Since the Born phase space is fully constrained by specifying any two of the three DIS variables x , y , and Q^2 there exists more than one double-differential cross section. The convention in `disorder` is to always return $\frac{d\sigma^2}{dx dQ^2}$ (in pb/GeV²) regardless of which of the two variables are fixed. The user can easily convert to $\frac{d\sigma^2}{dx dy}$ or $\frac{d\sigma^2}{dy dQ^2}$ by supplying a factor $\frac{Q^2}{y}$ or $\frac{x}{y}$ respectively. If only one of x , y , or Q^2 is specified then the appropriate single differential cross section is returned, i.e. $\frac{d\sigma}{dx}$ in pb, $\frac{d\sigma}{dy}$ in pb, or $\frac{d\sigma}{dQ^2}$ in pb/GeV², integrated over the other two variables. If none of the variables are fixed then the total cross section integrated over x , y , and Q^2 is returned in pb.

2.2 Applying P2B

The structure functions are by definition inclusive in all radiation and can therefore only provide predictions for quantities, like the inclusive cross sections, which depend on the Born kinematics of eq. (1) only. If we instead evaluate the structure functions on an observable sensitive to emissions, e.g. the transverse momentum of the hardest jet in the laboratory frame, we see that this will not give the right answer, as the real emissions are not included with their

correct-kinematics. In fact, when computing the coefficient functions that enter the structure functions, the real-emission diagrams are explicitly projected onto the Born kinematics.

The P2B method lifts this restriction by effectively replacing the Born-kinematics real-emission contributions in the structure functions with the correct kinematics ones. In practice whenever `disent` returns an event with some weight, we bin it once according to the true kinematics, and again projecting the kinematics to the underlying Born changing the sign of the weight. This last term, upon integration, will exactly cancel the real contribution in the structure functions, whereas the first term will provide the correct real matrix element. A detailed discussion of the method can be found in section 2 of Ref. [40].

As mentioned already in the Introduction, this procedure is trivial when applied to the Breit-frame kinematics. In this frame the outgoing parton has zero transverse momentum, and will therefore not contribute to any jet-sensitive observable, like the well-known thrust event-shape [49]. In the laboratory frame however, the jet kinematics are non-trivial even at Born-level, cf. eq. (5), and the P2B method as applied here will correctly describe single-jet production in this frame. The projections themselves are trivial because, as outlined in the section above, the Born kinematics are fully specified at all orders by the lepton (and proton) momenta, as given in eqs. (2)–(5). Hence computing the projections adds very little computational effort to the cross section calculation.

At this point it is worth reminding the reader that `disent` only includes the photon-mediated NC, and hence `disorder` only provides exclusive predictions for this channel. It should be possible to extend the code to include Z-mediation (including interferences) and CC, but we leave this for future work.

In principle P2B could be applied to the `disent` code without any major modifications besides the bug fix mentioned in the introduction, which has been implemented here. However a few significant modifications were introduced to allow for a more flexible integration of `disent` into `disorder`. The version of `disent` that we include in `disorder` is based on the version which can be found in `dispatch` [50], and which already included some minor modifications. In addition to the modifications present there, we have also introduced α as an input parameter, whereas before it was fixed to $1/137$. A number of parameters can also now be set on the command line as described below. Besides coding the actual interface to `disent`, the biggest modification introduced in `disorder` is that the `KPFUNS` subroutine now returns an array of weights corresponding to varying the factorisation scale by a factor two up and down. This allows for much faster evaluation of scale uncertainties compared to running the program three separate times. Additionally `disent` can now also use any scale defined in terms of x , y , and Q , and not just some multiple of Q . We provide a few different scale choices as documented below, but more can easily be implemented.

3 Running disorder

In this section we give instructions on how to compile and run `disorder`, giving a few examples of the use of the most common command line arguments. The code itself can be obtained from

<https://github.com/alexanderkarlberg/disorder>.

3.1 Compiling and prerequisites

A user should start by inspecting `README.md`. To compile `disorder` both `HOPPET` (v1.3.0 or later) and `LHAPDF` (tested with v6.5.4) [77] have to be installed on the machine. If both are installed in a location in the `$PATH` it is enough to run

```
mkdir build && cd build
cmake ..
```

```
make [-j]
```

from the main directory. This will create an executable `disorder` along with two auxiliary executables, `mergedata` and `getpdfuncert`. For non-standard installation of HOPPET and LHAPDF the paths can be specified like this

```
cmake -DHOPPET_CONFIG=/path/to/hoppet-config -DLHAPDF_CONFIG=/path/to/lhapdf-config
```

where the path should include the config-file itself (i.e. `/usr/local/bin/hoppet-config`). By default `fastjet` is not linked and only a skeleton analysis (`analysis/simple_analysis.f`) is compiled. To link `fastjet` run

```
cmake -DNEEDS_FASTJET=ON [-DFASTJET_CONFIG=/path/to/fastjet-config]
```

where the path to `fastjet-config` only needs to be specified if it is not in the user's `$PATH`. To compile a different analysis the user should first put it in the `analysis` directory (here we assume it to be called `my_analysis.f`), and then pass it to `cmake` through

```
cmake -DANALYSIS=my_analysis.f
```

The program has been found to compile on a Linux machine using the `gfortran v11.4.0` compiler and also on various MacOS systems.

3.1.1 The analysis framework

The code uses the POWHEG-BOX analysis framework, with some minor modifications. A few example analyses are included in the `analysis` directory. Any new analysis should be put here and the name of the analysis should be passed to `cmake` as described above. There are two mandatory routines in the analysis file, `define_histograms` and `user_analysis`. In the first routine one should define histograms like this (there are also routines available to book histograms with varying bins sizes)

```
call bookupeqbins('string_name', binsize, min, max)
```

The `user_analysis` routine takes as input

```
integer n
double precision dsig(maxscales), x, y, Q2
```

where `n` is the number of initial plus final state particles, `dsig` is the weights computed by `disorder` and `maxscales` is the maximum number of scales which is supported (currently 7). `x`, `y`, and `Q2` are the DIS variables.

Through the module `mod_analysis` the analysis has access to two arrays of momenta `pbreit(0:3,1:n)` and `plab(0:3,1:n)` in which the Breit and laboratory frame momenta are stored respectively. The first entry is the incoming lepton, the second the incoming parton, the third the outgoing lepton and the rest outgoing partons. The output of the analysis will be saved to the disk as outlined below. In the `user_analysis` routine the user should perform their analysis and fill histograms like this

```
call filld('string_name', obs_value, dsig)
```

where `obs_value` is the value of the observable to be binned, and `dsig` is the associated array of weights.

In the `aux` folder one may also find a script called `mergedata` that can perform various manipulations of the datafiles. In particular

```
./mergedata 1 {list of statistically equivalent files}
```

will take the average of all files and produce the file `fort.12` with the result. Running the script without any arguments will result in a list of possible uses of the script. The mergedata script is taken from the POWHEG-BOX as well.

3.2 Inclusive mode

The syntax for running the program is

```
./disorder -pdf LHAPDF_name [options]
```

Running the program without any other options than `-pdf` will compute the total inclusive cross section above the minimum Q value accessible in the PDF, and using default parameters everywhere. The user can get a list of most parameters which can be specified on the command line by running

```
./disorder -help
```

Here we describe the most common flags, but for a complete list of all parameters, and their use, the user should look through the file [src/mod_parameters.f90](#).

The program allows the user to specify limits on x , y , and Q through `-xmin`, `-xmax`, `-ymin`, `-ymax`, `-Qmin`, `-Qmax`, or to fix them through the options `-x`, `-y`, `-Q`. For instance to compute the cross section at $Q = 20$ GeV and $x > 0.01$ one would run

```
./disorder -Q 20 -xmin 0.01 -pdf LHAPDF_name
```

The program will perform a Monte Carlo integration in the ranges specified, using the integrator VEGAS [85]. If the phase space is fully constrained by fixing two of either x , y , and Q the program simply evaluates one point and returns the answer.

One can further specify the energy of the incoming lepton through `-Ellep`, the incoming hadron through `-Ehad`. By default the lepton is taken to be an electron but specifying `-positron` on the command line will change that. To use an incoming neutrino the user should specify `-neutrino`. If `-positron` is also specified the incoming lepton will be an anti-neutrino. The code computes the photon-mediated NC cross section only by default. To include the Z one can specify `-includeZ` and to include CC processes one can specify `-CC`. The inclusion of NC processes can also be controlled through the `-NC` flag. In fact, all logical flags can be prefixed by “no” to turn them off. Hence the below command line would run the program with CC processes only using a positron

```
./disorder -Q 20 -xmin 0.01 -noNC -CC -positron -pdf LHAPDF_name
```

The order of the calculation is by default NNLO but can be specified with one of the flags `-lo/-nlo/-nnlo/-n3lo`. If the user wants to compute PDF uncertainties, the flag `-pdfuncert` should be given. This flag will make `disorder` loop over all the members in the PDF, and combine their errors according to the routine `getpdfuncertainty` [86], native to LHAPDF. This also means that the program is slowed down proportionally to the number of PDF members (although the VEGAS grid only gets computed once and then stored so that the runs are fully correlated). If the PDF also includes α_s variations these are included in the PDF uncertainty by default. If the user wants the PDF and α_s uncertainties independently, then the flag `-alphasuncert` should be specified. Some care should be taken here, as in practice the code assumes that the α_s variations are contained in the last two PDF members, and simply separates them from the rest.

Renormalisation, μ_R , and factorisation, μ_F , scale uncertainties can be included by specifying the flag `-scaleuncert`. `disorder` uses the vector boson virtuality, Q^2 , as its default central scale, but can use any scale as long as it is defined in terms of x , y , and Q . A few central scales, μ , are currently implemented and can be accessed through the `-scale-choice` flag. The options are 0: M_Z , 1 (default): Q^2 , 2: $Q^2(1-y)$, 3: $\frac{Q^2(1-x)}{x}$. The program will then

compute a standard 7-point scale variation varying this scale by a factor of two up and down keeping $1/2 \leq \mu_R/\mu_F \leq 2$. On the screen the envelope of all 7 runs will be printed. The user can in principle also carry out arbitrary variations in individual runs by specifying `-xmur` and `-xmuf` on the command line. Here `xmur` is the ratio of μ_R/μ and similarly for `xmuf`.¹⁰

Finally the random seed can be set with the `iseed` flag. When the program terminates it will print results to screen but also save a number of files depending on the exact input. There is always a file called `xsct_nnlo_seed0001.dat`, where the `nnlo` and `seed0001` parts will vary depending on the order and seed, which contains a summary of the run, including the total and reduced cross sections.

The output of the analysis is printed to a number of `.dat` files, the number depending on the input, prefixed by `disorder_nnlo_seed0001_pdfmem000` where again the exact prefix will depend on the input. The output name also contains information on the seed, the PDF member and the renormalisation and factorisation scales if `-scaleuncert` is on. The user can specify a prefix to be added to all the files through the `-prefix` flag.

Since it is often not necessary to run an analysis in the inclusive mode, the user can simply turn this off with the `-no-analysis` flag.

Finally the user can control the number of VEGAS integration points through the two flags `-ncall1` and `-ncall2`. The first flag controls the number of points to use to set up the grids. Since the phase space is not complicated it is rarely necessary to increase the default of 10000. The second flag controls the number of points that are used for the actual integration. If one is not running an analysis, the default number of 100000 should give results that have better than permille level accuracy. If the user wishes for instance to bin the cross section in fine bins of x and Q^2 , this number will most likely have to be increased.

3.3 P2B mode

To turn on P2B it is enough to specify `-p2b` on the command line. Many of the flags described above can also be specified in this mode, with a few limitations

- `-CC`, `-neutrino`, and `-includeZ` are not supported,
- `-n3lo` is not supported,
- `-pdfuncert` and `-alphasuncert` are not supported.

Importantly, it is possible to run with the `-scaleuncert` flag which leads to a significant reduction in run-time compared to doing seven separate runs. When running in P2B mode it is furthermore of use to be able to control the number of calls to `disent`. This is done through the flag `-ncall2`, introduced already above.

We provide a small script to run on multiple cores on a single machine in [aux/runpar.sh](#).

3.4 Validating the code

The code comes with a script to validate that the results come out as expected. It can be run by entering `validation` and executing

```
./validate_or_generate.sh validate
```

¹⁰In practice it is faster to use the `-scaleuncert` flag as the program will only recompute what is needed for the variations rather than do a full event. However, at N³LO, in general, this is not true, due to the fact that the number of tables needed in HOPPET to carry out on-the-fly scale variations increases dramatically at this order, compared to using a fixed ratio of Q . Given how fast the code is, it is still the author's opinion that it is more convenient to use the on-the-fly variations.

Table 1: The inclusive and reduced cross sections at various orders in both NC and CC DIS. The setup is given in eq. (12). The aN³LO row is obtained using the approximate N³LO PDF set MSHT20an3lo_as118. Note that there is no Monte Carlo error on these numbers.

$$Q = 10 \text{ GeV}, \quad x = 0.01$$

	$\frac{\sigma_{\text{NC}}}{dx dQ^2}$ [pb/GeV ²]	δPDF	$\frac{\sigma_{\text{CC}}}{dx dQ^2}$ [pb/GeV ²]	δPDF	$\tilde{\sigma}_{\text{NC}}$	$\tilde{\sigma}_{\text{CC}}$
aN ³ LO	1932 ^{+7.05%} _{−4.86%}	0.972%	1.100 ^{+5.91%} _{−4.23%}	1.103%	0.8174	2.884
N ³ LO	1886 ^{+5.46%} _{−1.60%}	0.845%	1.080 ^{+4.55%} _{−1.32%}	0.914%	0.7980	2.829
NNLO	1895 ^{+1.50%} _{−1.18%}	0.840%	1.084 ^{+1.25%} _{−0.994%}	0.908%	0.8018	2.840
NLO	1952 ^{+3.66%} _{−4.43%}	0.810%	1.111 ^{+3.02%} _{−3.63%}	0.880%	0.8260	2.913
LO	2058 ^{+13.8%} _{−17.0%}	0.843%	1.163 ^{+11.4%} _{−14.1%}	0.885%	0.9708	3.050

The script builds the code and executes a number of tests designed to check the most important features of `disorder`, including both the NC and CC channels, the `fastjet` and LHAPDF interfaces, the automated PDF and scale uncertainty features, and P2B. The script assumes default installation paths for `HOPPET`, `fastjet`, and LHAPDF. A user can however manually change this by inspecting the script and adding the appropriate `cmake` flags at the beginning. The validation script runs in about 500 CPU seconds, or no more than a few minutes on a modern laptop, utilising the `parallel` program [87].

4 Benchmarks and results

In this section we show a few results obtained by running the code in both the inclusive and the P2B modes. The purpose is not to provide an exhaustive phenomenological analysis, but rather show the capabilities of `disorder` and to provide a few select results that can be used to either validate the code when running it, or to validate other programs in the future. All analyses used in this section can be found in the `analysis` directory, and the raw results can be found in the `paper_runs` folder.

We use `fastjet v3.4.1` for jet-clustering, and unless otherwise stated we collide electrons and protons using the MSHT20nnlo_as118 [88] PDF set using LHAPDF v6.5.4 and the following input parameters in all calculations

$$M_W = 80.398 \text{ GeV}, \quad M_Z = 91.1876 \text{ GeV}, \quad E_h = 920 \text{ GeV}, \quad E_l = 27.6 \text{ GeV}, \quad (12)$$

$$\alpha = 1/137, \quad \alpha_s(M_Z) = 0.118, \quad n_f = 5.$$

4.1 Inclusive results

The perhaps most fundamental question one can ask in DIS is “what is the total cross section for a given value of x and Q ?”. The answer to that question is given in table 1 for both the NC and CC channels at $Q = 10 \text{ GeV}$ and $x = 0.01$, at all available perturbative orders. The row aN³LO is obtained with the MSHT20an3lo_as118 [89] PDF set which includes approximate N³LO theoretical input. It is interesting to note that the inclusion of the approximate terms has an impact that is parametrically of the same order as the NNLO corrections. The PDF uncertainties stay more or less constant across all orders, which is not unexpected given that we use the same PDF at each order. To give a sense of the speed of the code, the combined results presented in the table, which corresponds to 325 different PDF members and hence

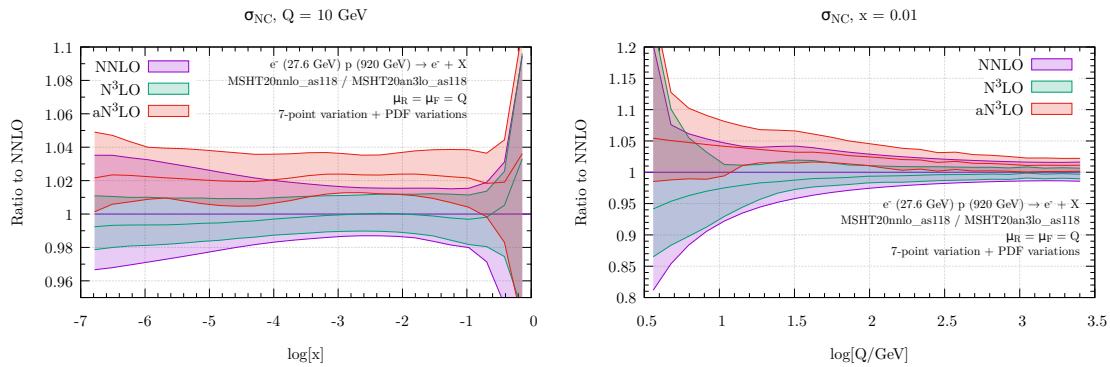

Figure 1: The NC cross section for fixed $Q = 10$ GeV differential in $\log x$ (left) and for fixed $x = 0.01$ and differential in $\log Q$ (right). We show NNLO (purple), N^3 LO (green), and aN^3 LO (red). The uncertainty band is obtained as the linear combination of scale and PDF uncertainties.

structure functions, took a total of 3.5 minutes to obtain on a laptop equipped with an Intel i9-10885H CPU.

In figure 1 we show the NC cross section for fixed $Q = 10$ GeV (left) or $x = 0.01$ (right), now only at NNLO, N^3 LO and aN^3 LO. The uncertainty bands are obtained as a linear combination of the scale uncertainty and the PDF uncertainty, and is typically dominated by the latter, in particular at N^3 LO. We observe that although the central prediction at aN^3 LO is in tension with the N^3 LO curve, it is contained within the NNLO scale uncertainty band, except at intermediate x values. It will be interesting to see, if the inclusion of the exact N^3 LO splitting functions, when they become available, will ameliorate this tension.

4.2 Exclusive laboratory frame results

To demonstrate the results of the code in P2B mode, we perform a jet analysis in the laboratory frame, based on Ref. [81], which probes the kinematic range accessible by the upcoming EIC. For this analysis we set $E_l = 18$ GeV, $E_h = 275$ GeV, and restrict the DIS kinematics by

$$25 \text{ GeV}^2 < Q^2 < 1000 \text{ GeV}^2, \quad 0.04 < y < 0.95. \quad (13)$$

We reconstruct jets in the laboratory frame using the anti- k_T algorithm [90] with $R = 0.8$. Jets are those that satisfy the following transverse momentum and pseudo-rapidity requirements

$$p_{t,j} > 5 \text{ GeV}, \quad |\eta_j| < 3. \quad (14)$$

In Fig. 2 we show the inclusive jet transverse momentum and rapidity at LO, NLO, and NNLO, in photon-induced NC DIS. For the transverse momentum the higher order corrections are moderate except for small values and close to the LO threshold of $p_{t,j} = Q$. The rapidity distribution on the other hand receives larger corrections. This is in part due to hard jets with $p_{t,j} > Q$ that can only arise at NLO and beyond. Here the scale variation bands do not cover the actual corrections, and it is obvious that one needs to go beyond NLO for reliable predictions. Of course one needs the full N^3 LO to assess the reliability of the NNLO result. However, from similar results in Ref. [40] it can be expected that the actual N^3 LO results will be mostly contained within the scale variation band at NNLO.

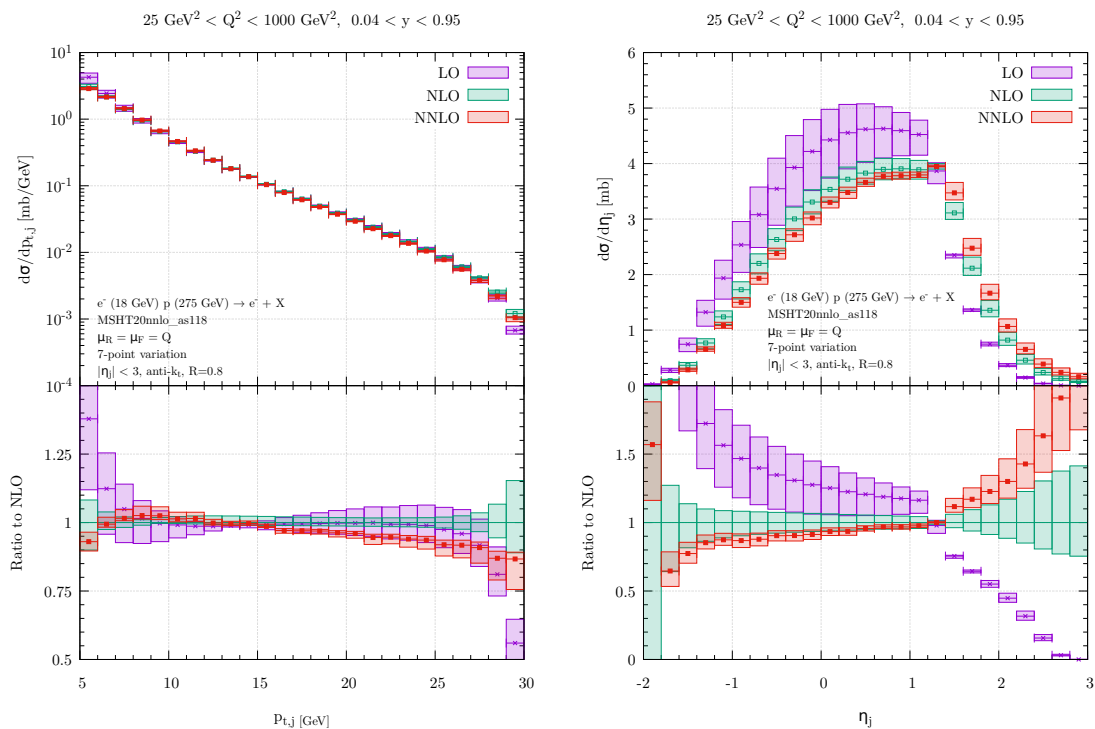

Figure 2: The NC cross section for fixed $Q = 10 \text{ GeV}$ differential in $\log x$ (left) and for fixed $x = 0.01$ and differential in $\log Q$ (right). We show NNLO (purple), $N^3\text{LO}$ (green), and $aN^3\text{LO}$ (red). The uncertainty band is obtained as the linear combination of scale and PDF uncertainties.

5 Conclusion

In this paper we have presented version 1.0.0 of a Fortran code, `disorder`, capable of computing massless DIS cross sections fully differentially at NNLO and inclusively at $N^3\text{LO}$. The code combines the NNLO structure functions from `HOPPET` and the NLO dijet calculation of `disent`, using the P2B method, thereby obtaining fully differential single-jet DIS predictions in the laboratory frame. In the inclusive mode the program includes all NC and CC contributions and can carry out both scale and PDF variations on the fly. Due to the underlying tabulation of the structure functions in `HOPPET`, the code is extremely fast, and a user can obtain cross section results at $N^3\text{LO}$ in a matter of seconds.

In the fully differential P2B mode, only photon-mediated DIS can be computed, and no PDF variations are currently implemented. It should in principle be possible to extend `disent` to full NC and CC, and this is something that is planned for a future release of the code. The extension to CC would in fact be very beneficial, as the Breit-frame cannot be reliably determined due to the undetected neutrino. Similarly the PDF variations could also be implemented, however this would require some serious restructuring of the code for it to be efficient. Extension of the code to handle incoming neutrino beams in the P2B mode, of relevance to the `FASER` [91] physics program, is also planned.

The upgrade of the code to handle $N^3\text{LO}$ fully differentially is however not currently planned. This is mainly due to the fact that this would require a complete replacement of `disent` with a proper NNLO dijet code, entailing a significant amount of work. Such a code would also be very slow compared to what is in place now, and it would defeat part of the attraction of `disorder` which is its speed. At LO and NLO a user can obtain differential re-

sults on a laptop running for a just a few minutes, and even reasonable NNLO results can be obtained on a multi-core machine running for an hour. N³LO results would inevitably require large resources on a High Performance Cluster.

Given the code's dependency on HOPPET, any developments therein will almost automatically propagate to `disorder`. In particular it is expected that the exact $\mathcal{O}(\alpha_s^4)$ splitting functions, as opposed to the approximations which are currently employed, will become available in HOPPET once they have been fully determined. This is currently the only missing piece needed to formally claim full N³LO accuracy for the structure functions. Similarly, were the massive DIS coefficient functions [92–99] to be implemented in HOPPET the structure functions in `disorder` could immediately be modified to accommodate this.

The code is intended to be user-friendly and to this effect comes with an interface to `fastjet` and LHAPDF and is run through a command line interface.

Acknowledgments

The author is grateful for many discussions with Andrea Banfi and Gavin Salam regarding `disent`, and for encouragement to publish `disorder`. The author also thanks Valerio Bertone for discussions about the DIS structure functions and Alex Huss for valuable cross-checks against results obtained with the NNLOJET code. The idea for the code originated while the author was working on Ref. [100].
