Abstract

Three-dimensional topological insulators (TIs) host helical Dirac surface states at the interface with a trivial insulator. In quasi-one-dimensional TI nanoribbon structures the wave function of surface charges extends phase-coherently along the perimeter of the nanoribbon, resulting in a quantization of transverse surface modes. Furthermore, as the inherent spin-momentum locking results in a Berry phase offset of π of self-interfering charge carriers an energy gap within the surface state dispersion appears and all states become spin-degenerate. We investigate and compare the magnetic field dependent surface state dispersion in selectively deposited Bi_2Te_3 TI micro- and nanoribbon structures by analysing the gate voltage dependent magnetoconductance at cryogenic temperatures. While in wide microribbon devices the field effect mainly changes the amount of bulk charges close to the top surface we identify coherent transverse surface states along the perimeter of the nanoribbon devices responding to a change in top gate potential. We quantify the energetic spacing in between these quantized transverse subbands by using an electrostatic model that treats an initial difference in charge carrier densities on the top and bottom surface as well as remaining bulk charges. In the gate voltage dependent transconductance we find oscillations that change their relative phase by π at half-integer values of the magnetic flux quantum applied coaxial to the nanoribbon, which is a signature for a magnetic flux dependent topological phase transition in narrow, selectively deposited TI nanoribbon devices.

1 Introduction

Quasi-one-dimensional structures of three-dimensional topological insulators (TIs) are of great interest, as they are predicted to host Majorana zero modes, when proximity coupled to an s-wave superconducting metal [1–3]. Two pairs of these exotic quasiparticle excitations can be used to encode the state of a topological quantum bit (qubit) [4, 5]. Large arrays of one-dimensional TI nanoribbons are envisioned for a scalable approach to define a quantum register of topological qubits [6, 7]. Novel epitaxial methods have been developed in order to grow TI nanoribbons selectively by molecular beam epitaxy (MBE) [8, 9]. On silicon hexagonal surfaces, partially covered by SiO₂ and amorphous Si₃N₄, this approach promises a high yield of selectively grown nanoribbons and highly scalable device networks.

The class of three-dimensional TI materials have Dirac surface states with linear dispersion and a unique helical spin texture as the spin of charge carriers is locked to their momentum [10–12]. When the phase-coherence length exceeds the perimeter of the nanoribbon, counterpropagating waves of surface charge carriers will self-interfere and their wave functions form standing waves that fit within the perimeter of the nanoribbon [13, 14]. As a result transverse-momentum subbands along the nanoribbon perimeter are quantized. Due to the inherent property of spin-momentum locking a Berry phase of π is picked up by charges that perform one full rotation in momentum space (one full rotation along the nanoribbon perimeter) [10, 15]. The boundary conditions of self-interfering charge carriers are therefore antiperiodic and cause the surface state spectrum to be gapped in narrow nanoribbon structures [13]. In order to restore a pair of gapless, linear Dirac surface subbands a magnetic flux of $\Phi = (l + 1/2)\Phi_0$ needs to thread the cross section of the nanoribbon [16–18]. Here $\Phi_0 = h/e$ is the magnetic flux quantum and $l = 0, \pm 1, \pm 2, \dots$ the transverse-mode index of quantized surface subbands. When the Dirac point resides close to the Fermi energy magnetic flux quantum-periodic Aharonov–Bohm-type (AB) magnetoconductance oscillations reflect the periodic appearance of the gapless, linear Dirac subbands as the system undergoes a topological phase transition [14, 19]. In bulk insulating TI nanoribbon devices, where only these linear Dirac subbands are populated by mobile charge carriers, a perfectly transmitted mode will establish as charge carriers can not scatter into states of opposite momentum and opposite spin [2, 3, 20].

In this research article we report on the electrical investigation of selectively-deposited Bi₂Te₃ micro- and nanoribbon field-effect devices at cryogenic temperatures. We first study the magnetic field and gate-voltage dependency of the selectively-deposited microribbon Hall

bar devices, where we identify a relatively large bulk background doping. Thin films as well as micro- and nanoribbon devices of TI materials often suffer from a high bulk charge carrier density [11, 21, 22]. Furthermore, we find that the top surface screens both the interior of the ribbon as well as the bottom surface from the electric field of the top gate electrode. As the perimeter of the microribbon exceeds the phase-coherence length of surface charge carriers [22] no AB-type oscillations are observed in the magnetoconductance data of the wide ribbon device. In TI nanoribbon devices, despite the high bulk carrier density, we identify surface-specific AB-type oscillations when applying a coaxial magnetic field. In bulk doped systems these AB-type magnetoconductance oscillations reflect the flux-periodicity of the surface state dispersion as the number of occupied transverse subbands below the Fermi energy changes [12, 16, 22–25].

The relative position of the quantized transverse subbands to the Fermi energy can be changed by accumulating or depleting charge carriers using a top gate-voltage, which effectively changes the occupation of transverse subbands along the nanoribbon perimeter P at fixed magnetic fields. Gate voltage-dependent magnetoconductance oscillation patterns have previously been reported to quantify the energetic spacing of quantized transverse-momentum subbands in rectangular HgTe nanoribbons defined by wet-chemical etching [18]. Due to the inhomogeneous electric field distribution we consider an effective capacitance model [18] adapted to our highly bulk-doped nanoribbon devices. We use this model to analyse the gate voltage dependency of transconductance within the nanoribbon devices at full and half-integer values of the magnetic flux quantum applied. We identify a flux dependent surface state dispersion and determine the transverse-momentum subband level spacing within the surface states of our selectively-deposited Bi_2Te_3 nanoribbon devices. Our analysis shows evidence of quantized transverse-momentum states on the perimeter of the TI nanoribbon and the electrostatic model treatment allows to distinguish these features from bulk effects or conventional two dimensional space charge layers without spin-momentum locking. Due to the scalability the results presented show that the selectively grown TI nanoribbon devices can be utilized for future Majorana related research and can ultimately be used in complex TI nanoribbon/superconductor heterostructures [9, 26].

2 Selectively deposited nanoribbon devices

2.1 Selective area epitaxy

Hall bar devices of different widths have been prepared by MBE following a selective area growth (SAG) approach [8, 9, 22]. Trenches of different widths W have been defined in a layer stack of 20 nm Si_3N_4 and 5 nm SiO_2 layer on top of a Si(111) substrate. First the oxide layer is created by thermal oxidation of the surface of the Si(111) substrate. After the oxidation the 20 nm thick Si_3N_4 layer is deposited using a low pressure chemical vapor deposition process. The ratio of the layer thicknesses of the SiO_2 buffer layer and the Si_3N_4 layer is chosen in order to compensate any strain these layers impose onto the Si(111) surface. The trenches are defined by a combination of wet- and dry-chemical etching using a positive electron beam resist. Reactive ion etching (RIE) (CHF_3 and O_2 gas mixture) has been used to transfer the trench structures from the electron beam resist into the nitride layer. After resist removal the SiO_2 within the nanotrenches is wet chemically removed using hydrofluoric (HF) acid, which renders the revealed Si(111) surfaces atomically smooth.

The Bi_2Te_3 binary TI has been grown in the Te-overpressure regime at $T_{\text{sub}}=290^\circ\text{C}$ selectively within the defined nanotrenches. After deposition of the TI layer a 2-3 nm-thin Al_2O_3 layer is deposited from a stoichiometric target. The dielectric capping layer is used to protect the TI ribbons from oxidation or other reactions with air.

2.2 Field effect in TI ribbon devices

For the microribbon Hall bar, we can consider a parallel plate capacitor geometry, and the applied gate potential V_g changes the two-dimensional charge-carrier density on the top surface as follows

$$\Delta n_{2D} = \frac{C}{e} \cdot \Delta V_g, \quad (1)$$

where $C = \epsilon A/d$ is the parallel-plate capacitance of the field-effect device, with ϵ the dielectric constant of the dielectric between gate and TI, A the area of the gated top surface of the TI and d the separation between gate and top surface.

In the case of a nanoribbon (a false-colored scanning electron micrograph of a 200 nm wide ribbon Hall bar is shown in Fig. 1 a)), the applied electric field (as schematically depicted in Fig. 1 b)) will simultaneously change the charge carrier density within the top surface (green), the bulk (red) and the bottom surface (green) [27,28]. Due to the geometry of devices investigated a non-homogeneous electric field distribution is induced and the capacitance becomes a position-dependent value $C(y(s), z(s)) \equiv C(s)$, with $s = [0, P]$ parameterizing the position coordinates along the perimeter P of the ribbon cross section. An effective capacitance model can be used to describe the perimeter-averaged gate effect on the topological surface states which extend *phase-coherently* across the complete perimeter of a nanoribbon or nanowire geometry, as considered in Ref. [18]. Here, we extend this approach to account for non-homogeneous Fermi level pinning along the ribbon perimeter. The average gate dependent energy of the surface state charge carriers can be determined following

$$\begin{aligned} \langle E(s, V_g) \rangle &= E_{DP} + \hbar v_F \sqrt{4\pi \left\langle \sqrt{n_{2D}^{TSS}(s) + C(s)V_g/e} \right\rangle} \\ &= E_{DP} + \hbar v_F \sqrt{4\pi [n_{2D}^{TSS,av.} + C_{eff}^{TSS} V_g/e]}, \end{aligned} \quad (2)$$

where v_F is the Fermi velocity, $\langle \dots \rangle$ denotes the average along the nanoribbon perimeter P , E_{DP} the Dirac point energy and n_{2D}^{TSS} the charge carrier density on the topological surface states (TSSs). $n_{2D}^{TSS,av.}$ is the average charge carrier density on the topological surface states and C_{eff}^{TSS} the effective capacitance. In systems where the surface state spectrum is initially pinned to the Dirac point ($n_{2D}^{TSS} = 0$) the equation simplifies to [18]

$$\langle E(s, V_g) \rangle = E_{DP} + \hbar v_F \sqrt{4\pi V_g C_{eff}/e}, \quad (3)$$

where the effective capacitance can be obtained by integration $C_{eff} = (1/P \int_0^P \sqrt{C(s)} ds)^2$. When the surface state spectrum is not initially pinned to the Dirac point, the initial average charge carrier density as well as the effective capacitance need to be considered. Molecular beam epitaxy grown Bi_2Te_3 micro- and nanoribbons [22] are unintentionally bulk doped during deposition. In such highly bulk conductive samples it can be assumed that the change in charge carrier density for small gate potentials applied is smaller than the initial charge carrier density $C(s)V_g \ll n_{2D}^{TSS}(s)$. With this assumption the effective capacitance in highly bulk doped systems can be calculated using

$$C_{eff} = \left\langle \sqrt{n_{2D}^{TSS}(s)} \right\rangle \left\langle C(s) / \sqrt{n_{2D}^{TSS}(s)} \right\rangle, \quad (4)$$

where the average charge carrier concentration can as well be determined through integration $\left\langle \sqrt{n_{2D}^{TSS}(s)} \right\rangle = n_{2D}^{TSS,av.} = (1/P \int_0^P \sqrt{n_{2D}^{TSS}(s)} ds)^2$.

2.3 Confinement in narrow TI nanoribbons

Here we investigate selectively deposited Hall bars of width $W = 1 \mu\text{m}$ and $W = 200 \text{ nm}$. Due to the SAG approach the layer thicknesses vary slightly, dependent on the width of the ribbon [22], which measure $t = 10 \text{ nm}$ and $t = 15 \text{ nm}$ for the wide microribbon and narrow nanoribbon, respectively. The perimeter $P \approx 2 \mu\text{m}$ of the wide microribbon is expected to be longer than the phase-coherence length of surface charges at $T = 1.5 \text{ K}$ [22]. The surface states of the wide microribbon are therefore expected to resemble the Dirac dispersion as observed in slabs of Bi_2Te_3 (schematically depicted in Fig. 1 c), left) [11, 29, 30]. The phase-coherence length is however expected to be comparable to the perimeter $P = 430 \text{ nm}$ of the narrow nanoribbon (see Sec. 3.2 and Fig. 4). The confinement in the narrow nanoribbon device is therefore expected to result in a quantization of transverse-momenta k_l [13, 31, 32] (schematically depicted in Fig. 1 c), right). The coaxial- and transverse-momentum-dependent

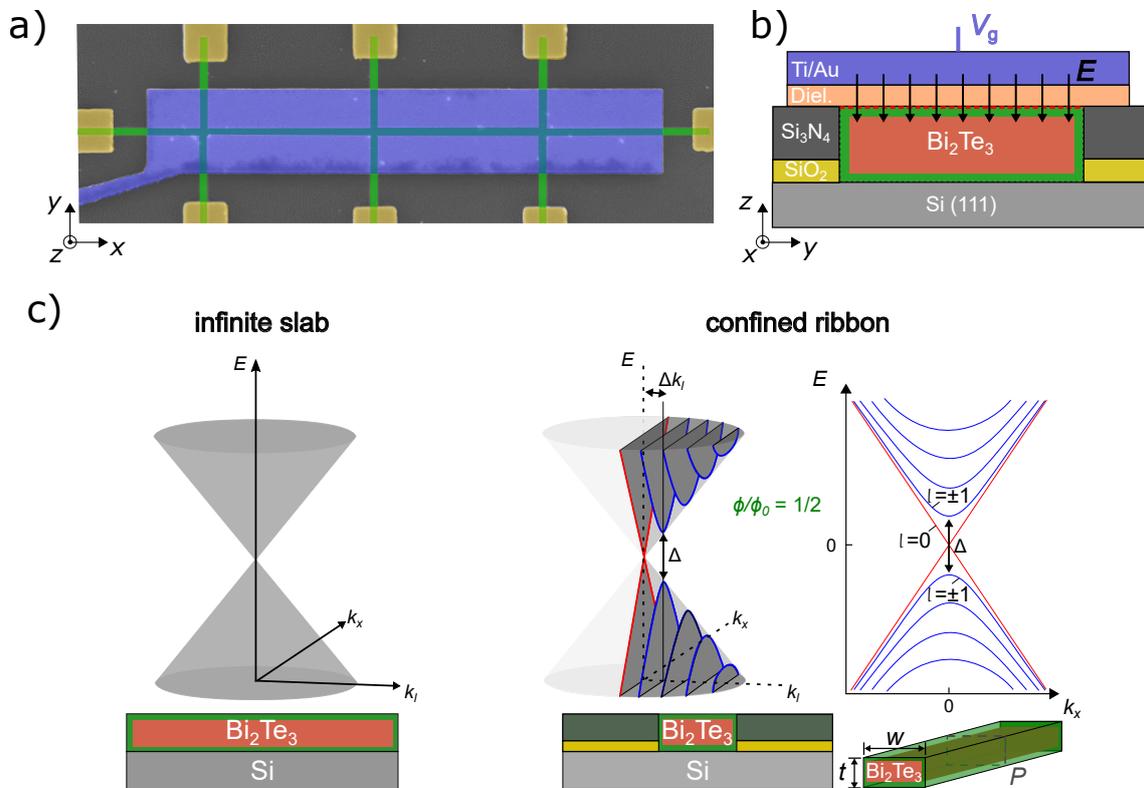

Figure 1: Dispersion relation in thin films and in confined nanoribbons of Bi_2Te_3 . a) A false-colored scanning-electron micrograph of a gated, 200 nm-wide Hall bar is shown. The contact electrodes on the TI (green) are highlighted in ochre and the top gate electrode is highlighted in blue. b) The device geometry including the SAG mask (yellow and dark grey), the Bi_2Te_3 nanoribbon (green and red highlighting the surface and bulk regions, respectively), the gate dielectric (rose) and the top gate electrode (blue) is schematically shown. c) The dispersion $E(k_x, k_l)$ of the surface states on the surfaces of an infinite slab of Bi_2Te_3 represent a Dirac cone. In narrow nanoribbon geometries the subband level spacing $\Delta k_l = 2\pi/P$ increases with decreasing nanoribbon perimeter $P = 2 \cdot (W + t)$, where W and t are the width and the thickness of the nanoribbon, respectively.

energy dispersion $E(k_x, k_l)$ within the confined nanoribbon structure is expressed by [13]

$$\begin{aligned} E(k_x, k_l) &= \pm \hbar v_F \sqrt{k_x^2 + k_l^2} \\ &= \pm \hbar v_F \sqrt{k_x^2 + \left(\frac{2\pi(l + 1/2 - \Phi/\Phi_0)}{P} \right)^2}, \end{aligned} \quad (5)$$

where k_x is the coaxial-momentum and $k_l = 2\pi(l + 1/2 - \Phi/\Phi_0)/P$ the confined transverse-momentum, with $\Phi_0 = h/e$ being the magnetic flux quantum. The nanoribbon dispersion is characterised by quantized transverse-momentum subbands of quantum number $l = 0, \pm 1, \pm 2, \dots$. Only for an applied magnetic flux $\Phi/\Phi_0 = l + 1/2$ there is a state at zero energy. Without applied magnetic flux or at other values of the magnetic flux applied the surface state dispersion features a finite energy gap around zero. The size of this energy gap in the surface state spectrum of quantized transverse modes is given by [13]

$$\Delta = \frac{2\pi v_F \hbar}{P}. \quad (6)$$

For an applied magnetic flux of $\Phi = \Phi_0/2 = h/2e$ the energy dispersion for the $l = 0$ transverse-momentum state is linear and offers zero-energy solutions. A pair of gapless, linear Dirac surface subbands establishes. When the magnetic flux further increases the surface state spectrum will again be gapped. The topological phase transition can be observed with a period of one full integer flux quantum [14].

3 Electrical characterization of micro- and nanoribbon field effect devices

3.1 Gate-dependent microribbon Hall measurements

Devices have been characterized using a variable temperature insert (VTI) cryostat with 1.5 K base temperature. Magnetic fields of up to 13 T field strength can be applied perpendicular and coaxial to the TI ribbon. By applying an a.c. current bias along the microribbon Hall bar the longitudinal magnetoresistance R_{xx} as well as the Hall resistance R_{xy} have been determined in a perpendicular magnetic field using standard lock-in techniques. The Hall resistance R_{xy} and the longitudinal magnetoresistance R_{xx} have been determined as a function of the gate voltage V_g . For the 1 μm -wide ribbon Hall bar a 15 nm-thick HfO_2 ($\epsilon_r = 18.75$) dielectric layer has been deposited by atomic layer deposition. Using a source-meter the leakage current has been determined to be negligible up to a top gate voltage of $|V_g| \leq 16\text{ V}$ ($I_{\text{leakage}} \leq 1\text{ nA}$). The anticipated initial band alignment is schematically depicted in Fig. 2 a). The bulk band gap for Bi_2Te_3 measures about $E_{\text{gap}} = 165\text{ meV}$ [29]. In previous measurements on selectively-deposited Bi_2Te_3 Hall bar structures it has been observed that the bands on the bottom surface bend towards the *p*-type Si(111) substrate [22] and the Fermi energy from an analysis of Shubnikov–de Haas oscillations has been determined to reside 90 meV above the Dirac point, which is buried within the bulk valence bands [33]. On the top surface angle-resolved photoemission spectra (ARPES) show that the Fermi energy resides within the bulk conduction band, about 70 meV above the bulk conduction band minimum [33, 34]. By performing Hall measurements the initial charge carrier density in the investigated devices can be determined. From Hall measurements at $V_g = 0$ (shown in Fig. 2 b), grey curve) the Hall slope is determined ($A_H = dR_{xy}/dB$) and the two-dimensional charge carrier density has been calculated to be $n_{2D} = (A_H e)^{-1} = 8.5 \times 10^{13}\text{ cm}^{-2}$. In Hall measurements the combined charge carrier density of the materials bulk and the surface states is probed. From previous studies of

Shubnikov–de Haas oscillations the charge carrier density on the bottom surface has been identified as $n_{2D,bot} = 5.3 \times 10^{11} \text{ cm}^{-2}$ [22]. From ARPES measurements a top surface charge carrier density of $n_{2D,top} = 8.2 \times 10^{12} \text{ cm}^{-2}$ can be inferred [33, 34] leaving a bulk charge carrier density of $n_{2D,bulk} = 7.6 \times 10^{13} \text{ cm}^{-2}$. Results therefore indicate a high density of bulk charges. The intrinsic n -type doping of the bulk is due to Te antisite defects in Bi_2Te_3 [11, 21]. Assuming an effective mass of $m^* = 0.58 m_e$ [35] the Fermi energy in the bulk can be estimated to lie about 100 meV above the conduction band minimum.

When a negative gate voltage $V_g < 0$ is applied to the top gate electrode, electronic charges on the top surface of the TI will be depleted. As a result, the Hall slope in Fig. 2 b) in-

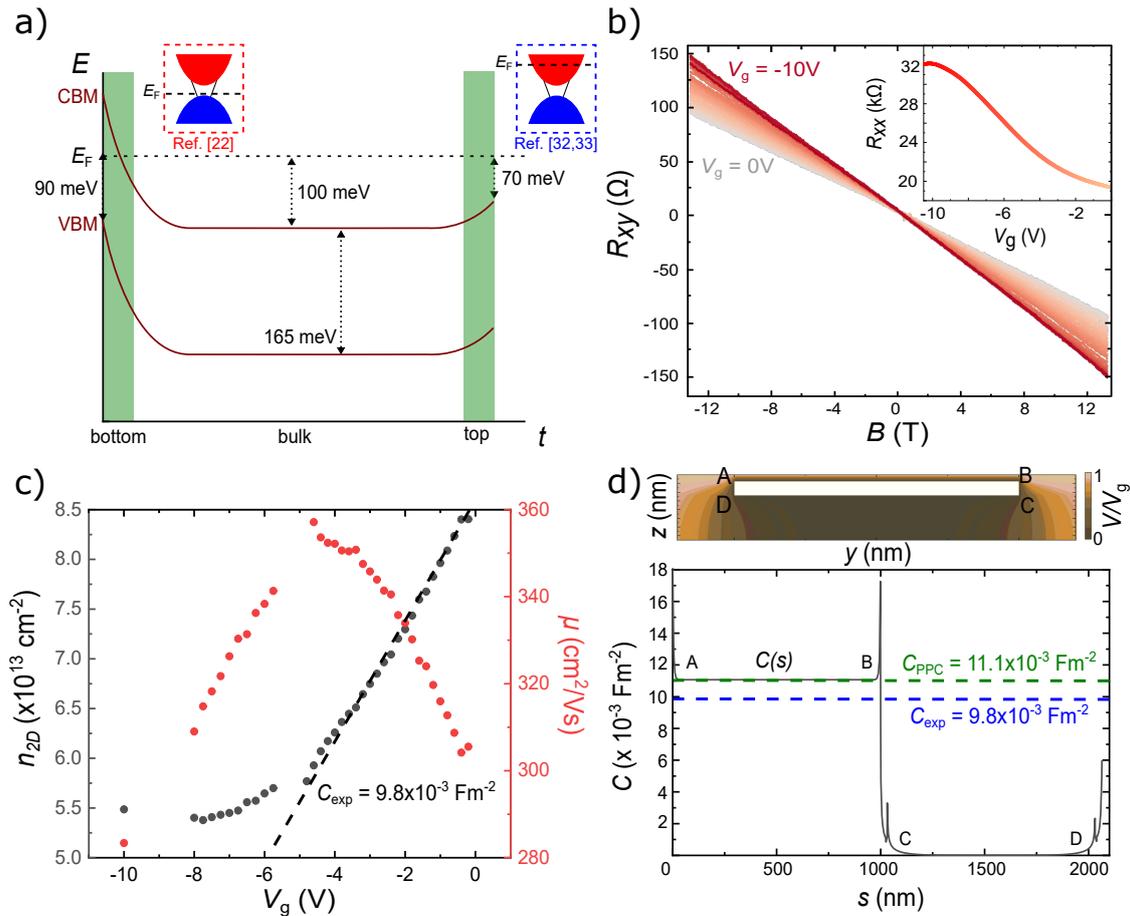

Figure 2: Gate-dependent Hall- and longitudinal resistance of the $1 \mu\text{m}$ wide Hall bar. a) Expected relative position of the Fermi energy within the bulk as well as on top and bottom surface of the ribbon device. b) Hall resistance R_{xy} measurements at different gate voltages V_g . The extracted Hall slopes dR_{xy}/dB have been used to evaluate the sheet carrier concentration n_{2D} shown in c) (black dots). The mobility μ values (red dots) have been evaluated by considering the gate-dependent sheet resistance R_S , extracted from the gate-dependent longitudinal resistance $R_{xx}(V_g)$ at zero magnetic field shown in the inset of b). In d) the simulated relative gate potential V/V_g (top) and calculated position dependent capacitance $C(s)$ (bottom) along the microribbon perimeter P are displayed. The dashed blue line represents the experimentally determined capacitance from c), while the dashed green line represents the estimated capacitance on the top surface considering a parallel plate capacitor model.

creases. Simultaneously, the longitudinal resistance R_{xx} , shown in the inset of Fig. 2 b), increases as well. Charge carrier density as well as mobility values ($\mu = L \cdot (WR_{xx}A_H e)^{-1}$ with L being the channel length), as determined from the $R_{xx}(V_g)$ and $R_{xy}(V_g)$ data, are shown as a function of the applied gate voltage in Fig. 2 c). In between $0V \geq V_g \geq -5V$ the charge-carrier density decreases linearly. As the amount of charge-carriers decreases, the mobility value increases gradually from an initial value of about $300 \text{ cm}^2/\text{Vs}$ at zero gate voltage to a value of about $360 \text{ cm}^2/\text{Vs}$ at $V_g = -5V$. The increase in mobility can be explained as bulk scattering of surface charges on the top surface is reduced [36]. From a linear fit to the gate-dependent charge-carrier density (following Eq. 1) in between $0V \geq V_g \geq -5V$ (dashed black line), a capacitance of $C_{\text{exp}} = 9.8 \times 10^{-3} \text{ Fm}^{-2}$ can be estimated. Given this experimentally-determined capacitance the charge-carrier density on the top surface will be depleted at $\Delta V_g = (e \cdot 8.2 \times 10^{16} \text{ m}^{-2}) / 9.8 \times 10^{-3} \text{ Fm}^{-2} = -1.3 \text{ V}$. As the linear trend of the gate voltage dependent charge-carrier density exceeds this value it can be concluded that both bulk and surface charges are depleted simultaneously. In the regime below $V_g \leq -5V$ the charge-carrier density saturates, while the mobility values decrease gradually. It can be assumed that the Fermi energy on the top surface drops below the conduction band, rendering charge accumulation more difficult [28, 37]. Since the Hall slope does not change sign the majority of bulk carriers, however, remains n -type throughout the range of gate voltages applied.

The experimentally-determined capacitance of the microribbon field-effect device is compared to the geometrical capacitance of the device. Therefore the relative gate potential V/V_g over the perimeter of the device as shown in Fig. 1 c) is simulated. A generalized Poisson solver is applied to a finite-element mesh of 35.000 points on a regular square lattice of 1 nm spacing in the yz -plane (for details on the simulation of the electrostatic behavior of the devices, the reader is referred to the Appendix). For the simulation the surface of the material is treated as a perfect metallic conductor i.e., the electric field cannot penetrate the interior of the microribbon. The results are shown in the top part of Fig. 2 d), displaying $C(s)$ the position dependent local capacitances along the microribbon perimeter P as described in Sec. 2.2. As charges on the top surface effectively screen both the interior and the bulk from the electric field, the local capacitance on the bottom surface drops to zero. As only charge carriers close to the surface of the microribbon are depleted the system resembles a parallel plate capacitor (PPC) geometry. The capacitance on the top surface is calculated to be $C_{\text{PPC}} = \epsilon_r \epsilon_0 A / d = 11.1 \pm 0.5 \times 10^{-3} \text{ F/m}^2$ (see green dashed line in Fig. 2 d)), with $\epsilon_r = 18.8 \pm 0.9$ the relative permittivity of the 15 nm thick HfO_2 layer. The experimentally determined value of the capacitance C_{exp} is highlighted as dark blue dashed line. The difference in the experimentally determined capacitance and the calculated capacitance using the PPC model on the top surface of the microribbon can be explained by small differences of the dielectric constants or the layer thicknesses of the layers involved compared to the values used in the simulation.

3.2 Magnetic field and gate voltage dependent conductance oscillations in nanoribbons

For the narrow nanoribbon Hall bar a 100 nm-thick LaLuO_3 ($\epsilon_r = 32$ [38]) dielectric layer has been deposited by pulsed-laser deposition. Applied gate voltages result in a smaller change of the charge carrier density compared to previously analysed microribbon field effect devices. This results in a better resolution when investigating electric field dependent transconductance oscillations. Leakage currents in the nanoribbon field-effect devices are negligible up to gate voltages of $|V_g| \leq 35 \text{ V}$.

Due to confinement, the topological surface-state spectrum is expected to be quantized, forming transverse-momentum subbands [13] following Eqs. 5 and 6. The magnetic flux dependency of the quantized subband dispersion of topological surface charges along the perimeter of the nanoribbon result in Aharonov–Bohm (AB) [39, 40] type oscillations that have a typical

h/e periodicity. Periodic AB oscillations have previously been reported for different topological insulator materials [16, 23, 25, 41–43] and also recently for selectively-deposited Bi_2Te_3 nanoribbon devices of different cross sectional areas [22]. For a 200 nm wide Bi_2Te_3 nanoribbon field-effect device presented here the longitudinal magnetoconductance $G_{xx}(B)$ (black curve) has been measured in magnetic fields up to 13 T and equivalently show AB-type oscillations, as exemplary shown in Fig. 3 a) at $V_g = -10\text{V}$. These oscillations have been measured to be reproducible after two alternate cooldown cycles and can be distinguished from universal conductance fluctuations by studying the dependency of the oscillation frequency with respect to the angle in between the nanoribbon and the applied magnetic field [22]. The periodicity of these oscillations implies that transport along the wire circumference is non-diffusive [44]. For interference of time-reversed paths in the diffusive limit $h/(2e)$ periodic oscillations are expected. Due to a strong background, mainly due to the weak antilocalization (WAL) effect, the AB-type oscillations are better visible, when subtracting a slowly varying background ($\delta G_{xx}(B)$, red curve). The background is created using a Savitzky–Golay filter with an averaging window of 3001 data points (corresponding to a range of 3 T). The applied magnetic flux $\Phi = B \cdot S$, where S is the cross section of the nanoribbon, is displayed normalized to

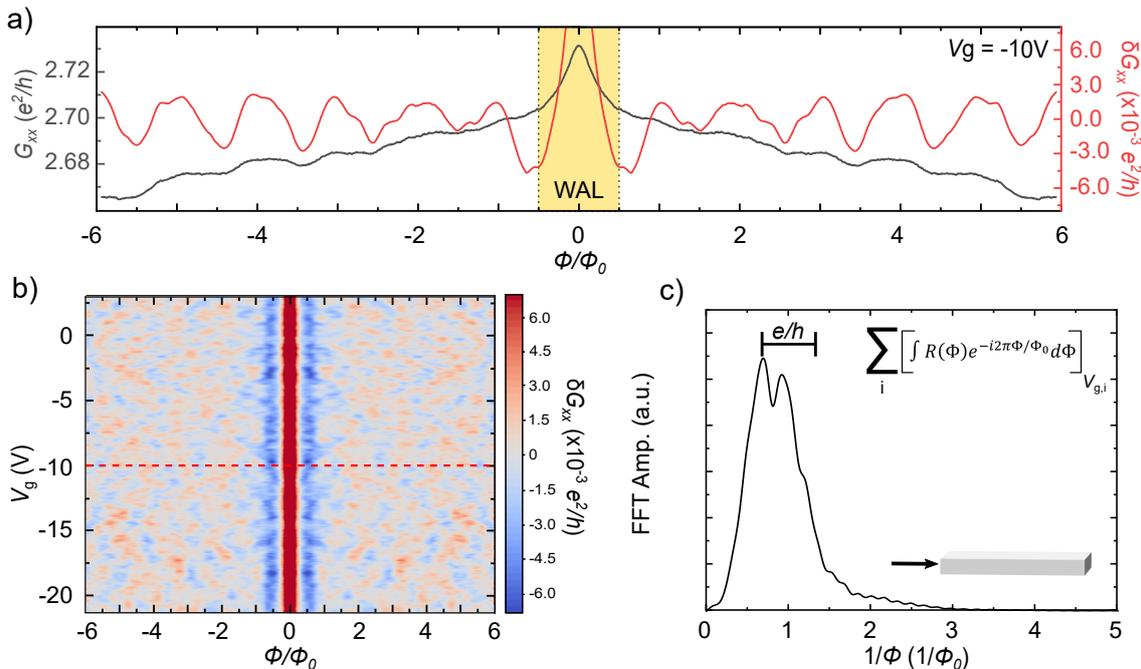

Figure 3: Gate-dependent magnetoconductance oscillations of the narrow nanoribbon in a parallel applied magnetic field. a) The magnetoconductance of a narrow nanoribbon device shows periodic Aharonov–Bohm oscillations, exemplary shown at a gate voltage of $V_g = -10\text{V}$ before (black curve) and after subtracting a slowly varying background (red curve). The low field is governed by the weak antilocalization effect (WAL). b) A set of magnetoconductance measurements performed at different gate voltages V_g . Each δG_{xx} curve shows a dominant WAL feature at low fields ($\Phi/\Phi_0 \sim 0$, red area) as well as flux quantum-periodic, symmetric oscillations at higher magnetic field strengths ($|\Phi/\Phi_0| > 0$). The flux-quantum periodicity of observed oscillations is further verified in the fast Fourier transformation performed on each dataset. In c) the sum of all FFT amplitudes of each respective scan are shown. The scale bar highlights the error of expected frequencies for the observation of flux-quantum periodic AB-type oscillations due to geometric uncertainty.

the magnetic flux quantum Φ_0 . As observed before [22], the cross sectional area determined from the flux periodicity $S = 2 \times 10^{-15} \text{ m}^2$ of the AB-type oscillations is slightly smaller than the geometrically determined cross sectional area $S = 2.6 \times 10^{-15} \text{ m}^2$. This has previously been attributed to the actual penetration depth of the wave function of the topological surface states [45], effectively reducing the cross sectional area. When applying a gate voltage, the position of the quantized transverse-momentum subbands with respect to the Fermi energy changes. The transconductance through the nanoribbon changes periodically dependent on the relative position of the subbands. Minima in the gate voltage dependent transconductance $G(V_g)$ thereby correspond to the Fermi energy residing at the edge (energetic minimum) of a transverse-momentum subband. At these points scattering is enhanced due to an increase in the density of states (van Hove singularities) [18]. When half a flux quantum is applied the energetic position of the subband minima are maximally shifted and the transconductance oscillations as a function of the applied gate voltage are shifted by $\Delta\phi = \pi$ [13, 19]. Please note that these type of phase shifts are not yet a proof for the topological nature of the transverse subbands involved. In confined systems, this phase shift of AB oscillations will also be observed in topologically trivial systems [46]. In the following the dependency of the magnetoconductance as a function of an applied gate voltage and an applied coaxial magnetic field $G(V_g, B)$ in the narrow nanoribbon device are investigated. Following the geometry argument (cf. Eq. 6) the anticipated spacing of individual subbands measures $\Delta = 4.5 \text{ meV}$.

For gate voltages in between $3 \text{ V} \geq V_g \geq -21 \text{ V}$ the magnetoconductance modulations (after subtracting a smooth background) as a function of the applied magnetic flux and the gate voltage $\delta G_{xx}(\Phi, V_g)$ are shown in Fig. 3 b). The low-field data in between $0.5 \geq \Phi/\Phi_0 \geq -0.5$ is dominated by the WAL effect and is generally neglected in the following analysis. At higher magnetic fields AB-type oscillations that vary with the applied gate voltage can be observed. For each magnetic field sweep a fast Fourier transformation (FFT) is performed and the sum of all resulting FFT amplitudes is taken. The results are shown in Fig. 3 c) and show a clear peak around $1/\Phi = 1/\Phi_0$ corresponding to AB-type oscillations of period Φ_0 . The error bar in the graph takes into account the deviation of the geometrically defined cross sectional area. The amplitude of these oscillations in quasi-ballistic systems is anticipated to be e^2/h [13, 24, 45] as each subband acts as a single ballistic channel. In measurements presented here the observed AB-type oscillations have an amplitude of a fraction of a single conductance quantum. While the periodicity of observed oscillations hints towards ballistic transport within the perimeter of the nanoribbon, the transport along the main axis of the nanoribbon exceeds both the elastic mean free path as well as the phase-coherence length. In such quasi-ballistic systems the amplitude of AB oscillations is smaller than the expected e^2/h amplitude in purely ballistic systems [46].

Observed Φ_0 -periodic AB oscillations show that the surface charges interfere on the nanoribbon perimeter phase-coherently. In order to quantify the phase-coherence length of surface state charges on the nanoribbon perimeter we evaluate the temperature dependency of the AB-type oscillations at a fixed gate voltage of $V_g = -12 \text{ V}$. The magnetoconductance modulations δG_{xx} in between $T = 1.5 \text{ K}$ base temperature up to $T = 30 \text{ K}$ are shown in Fig. 4 a). The AB oscillation amplitudes for two different peak positions (black square and red circle) are extracted and plotted as a function of the temperature T in Fig. 4 b). From the decay of the AB oscillation amplitude the phase-coherence length can be estimated following $\delta G(T) \propto \exp(-P/l_\phi(T))$ [47]. The $\delta G_{xx}(T)$ data is well fitted using the exponential decrease shown in Fig. 4 b). Such an unusual temperature dependency of the AB oscillation amplitude has been shown in 3D TI nanowires before [18, 48] and is due to a weak coupling of the ballistic surface charges to a fluctuating environment. From the fit we deduced a phase-coherence length of $l_\phi(T = 1 \text{ K}) = 1.65 \pm 0.17 \mu\text{m}$ at 1 K.

After identifying phase-coherent AB oscillations on the nanoribbon perimeter we now fo-

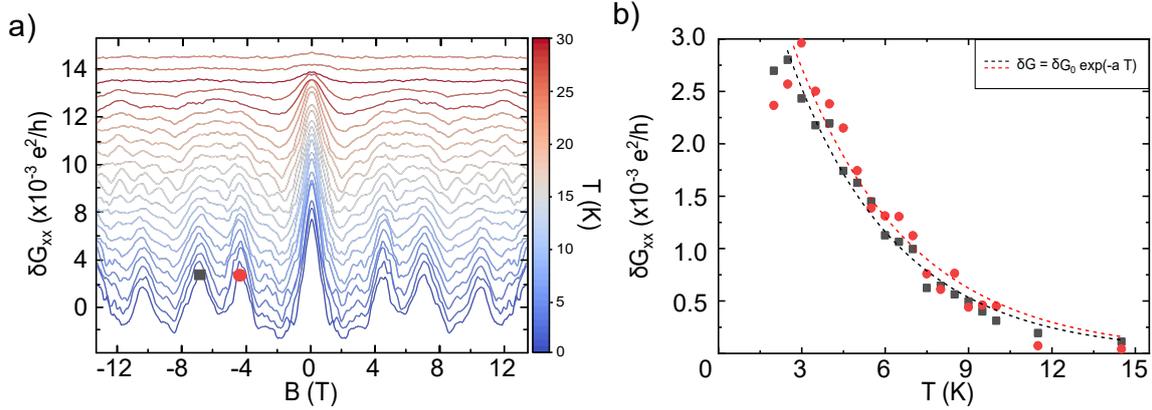

Figure 4: Temperature dependency of AB-type oscillations at $V_g = -12$ V. a) The background subtracted magnetoconductance data δG_{xx} of the narrow gated nanoribbon is shown at different temperatures. The temperature-dependent oscillation amplitude at $B = \pm 4.15$ T (black circles) and at $B = \pm 7.1$ T (red circles) is shown in b). An exponential fit has been performed to both datasets. An exponential fit as described in the main text is performed on both curves and the best fits are highlighted as a dashed black and dashed red line, respectively.

cus on the quantitative description of the subband level spacing of confined states. Analogous to the analysis procedure described by Ziegler et al. [18] we take the average of line cuts taken at multiples of integer values $i \cdot \Phi_0$ and multiples of half-integer values $(i + 1/2) \cdot \Phi_0$ of the magnetic flux quantum from Fig. 3 b). In this analysis the zero flux and the $\pm \Phi_0/2$ line cuts are excluded, due to the strong influence of the WAL feature in this region. The resulting curves are shown in Fig. 5 a) for applied gate voltages in the range of -2 V $\geq V_g \geq -12$ V. Both curves show a clear anticorrelated behavior, where maxima in the red curve coincide at the same gate voltage with minima of the black curve. As discussed before these minima in the transconductance as a function of the gate voltage are due to van Hove singularities at the edge of each transverse-momentum subband [18].

The anticorrelated maxima (minima) in the red (black) curve are indexed as indicated in Fig. 5 a). The running index N is thereby a relative value with respect to the number of occupied subbands N_0 at $V_g = 0$. Since for Bi_2Te_3 the Dirac point lies within the bulk valence band ($E_F - E_{\text{DP}} \approx 300$ meV) [12, 29, 33, 34] it is not possible to identify the initial number of occupied subbands. The number of occupied subbands is, however, effectively reduced by applying a negative gate voltage $V_g < 0$. In the range of applied gate voltages (0 V $\geq V_g \geq -21$ V) a total of more than 60 anticorrelated extrema have been identified, where the energetic spacing in between two subbands has been estimated to measure about $\Delta = 4.5$ meV (cf. Eq. 6). It is therefore likely that within the range of gate voltages applied ($N \cdot \Delta = 270$ meV) the Dirac point moves close to the average Fermi energy. The indexed anticorrelated minima are displayed versus the absolute value of the gate voltage applied in Fig. 5 b). At every conductance minimum in the gate-dependent transconductance the Fermi wavevector can be related to the amount of occupied subbands by $k_F = k_0 - N \Delta k_l$. Depending on the spin-degeneracy of the system, the Fermi wave vector can also be expressed following $k_F = \sqrt{(4\pi/g_s)n_{2\text{D}}^{\text{TSS}}}$, with the spin degeneracy factor $g_s = 1$ for topologically non-trivial and $g_s = 2$ for topologically trivial states. The gate-dependent subband filling can therefore be expressed following [18]

$$V_g - V_0 = \frac{g_s e}{4\pi C_{\text{eff}}^{\text{TSS}}} \left[2k_0(N - N_0)\Delta k_l + (N - N_0)^2 \Delta k_l^2 \right]. \quad (7)$$

The initial values are taken $V_0 = 0$ and $N = N_0$ to consider the relative change from the

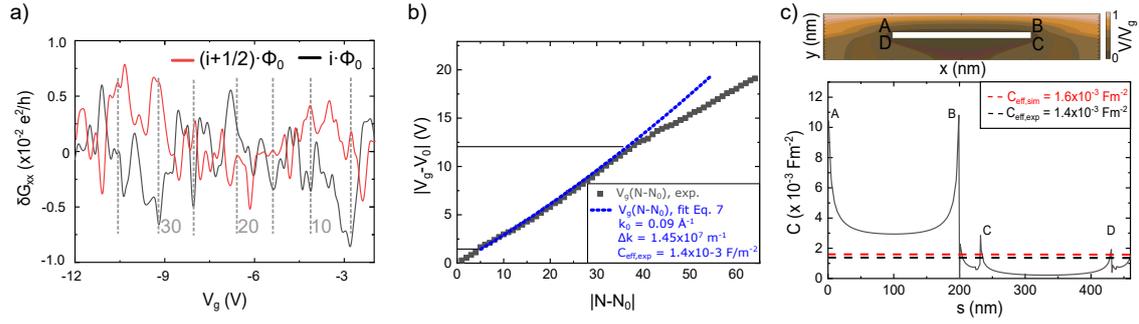

Figure 5: Gate-dependent subband spacing in the narrow nanoribbon. a) The average oscillation pattern of line-cuts at full integer (black curve) and half-integer (red curve) values of the magnetic flux quantum extracted from Fig. 4 a) are shown. The grey dashed lines show the extracted subband indices N , which are shown in b) as a function of the absolute applied gate voltage V_g . The black lines indicate the range of values shown in a). The blue dashed line indicates the fit performed following Eq. 7 and the values for the best fit performed are mentioned within the inset. c) Simulated relative gate potential V/V_g along the perimeter of the nanoribbon (top) and calculated local capacitances $C(s)$ (bottom).

initial occupation of subbands at zero gate voltage. The initial Fermi wave vector can be determined from the effective charge-carrier density $k_0 = \sqrt{4\pi n_{2D}^{\text{TSS,av.}}(V_g = 0)} = 0.09 \text{ \AA}^{-1}$. The subband spacing within the model in above equation can be approximated from the effective geometry of the nanoribbon as obtained from the periodicity of the AB oscillations $\Delta k_l = 2\pi/P = 1.55 \times 10^7 \text{ m}^{-1}$. The only free parameter left for the fit is the effective capacitance $C_{\text{eff}}^{\text{TSS}}$. For $g_s = 1$, indicating the subband spacing in topologically non-trivial surface states, the best fit performed is shown in Fig. 5 b), blue curve. The effective capacitance from the fit measures $C_{\text{eff}}^{\text{TSS}} := C_{\text{eff,exp}} = 1.4 \times 10^{-3} \text{ Fm}^{-2}$. For absolute gate voltages above $|V_g| \geq 12 \text{ V}$ the gate voltage needed to shift another subband through the Fermi level decreases. When the Dirac point moves closer to the Fermi energy the charge carrier density within the surface states changes more abruptly and the approximation to get Eq. 4 is no longer valid. Therefore the evaluation of the effective capacitance is restricted to the range of gate voltages in between $3 \text{ V} \leq |V_g| \leq 12 \text{ V}$.

The experimentally determined value for the effective capacitance is compared to the effective capacity determined from the electrostatic model discussed in Eqs. 1-4. The relative gate potential on the nanoribbon perimeter is determined using previously mentioned Poisson solver. The results of the simulations are shown in Fig. 5c) (top). A line cut (A-B-C-D-A) along the nanoribbon perimeter P is extracted and the local capacitances $C(s)$ are calculated and shown as solid black line in Fig. 5c) (bottom). From these values the effective capacitance has been evaluated to be $C_{\text{eff,sim}} = 1.6 \times 10^{-3} \text{ Fm}^{-2}$, which matches the experimentally determined effective capacitance quite well. Within the graph both the experimentally determined effective capacitance $C_{\text{eff,exp}}$ (black dashed line) and the effective capacitance determined from our electrostatic model $C_{\text{eff,sim}}$ (red dashed line) are highlighted. In order to rule out the possibility of a topologically trivial accumulation layer on the nanoribbon perimeter, we have also performed a fit using a spin degeneracy factor of $g_s = 2$, for which the effective capacitance measures $C_{\text{eff,exp}} = 2.9 \times 10^{-3} \text{ Fm}^{-2}$. This value differs greatly from the calculated effective capacitance. As we observe coherent states on the nanoribbon perimeter indicated by AB-type oscillations only an effective model for the capacitance is physically reasonable.

4 Conclusions

We have electrically characterized selectively-deposited Bi_2Te_3 micro- and nanoribbon field-effect devices at cryogenic temperatures and used an electrostatic model to investigate the geometry dependence of the topological surface state dispersion. Our model considers that in Hall measurements on the microribbon Hall bar device, the Bi_2Te_3 layer has been identified to be strongly bulk conductive. Additionally, the device geometry results in an inhomogeneous gate potential profile, with the bottom surface being effectively screened from the electric field of the top gate potential. For that reason the change in charge carrier density of the microribbon Hall bar device is captured by a parallel plate capacitor model. Surface charges and bulk charges close to the top surface are being depleted simultaneously, which is verified by comparing the effective capacitance determined from the gate voltage dependent change of the charge-carrier density to the calculated capacitance on the top surface. This model is limited by the observation that the charge carrier density decreases linearly first but then saturates. The saturation most likely occurs as charges from the top surface are being depleted while the bulk of the device remains highly conductive. The majority of charge-carriers in Hall measurements stay n -type throughout the whole range of gate voltages applied.

Unlike the wide microribbon field-effect device phase-coherent states span around the perimeter of the nanoribbon. Due to the geometrically well defined coherent conductance paths on the perimeter of the nanoribbon these transverse-momentum states are flux sensitive, resulting in magnetic flux quantum-periodic AB-type oscillations. The phase-coherence length from the temperature dependency of the AB oscillation amplitude $l_\phi(T = 1\text{K}) = 1.65 \pm 0.17 \mu\text{m}$ has been determined to be larger than the perimeter P of the nanoribbon device. We identify the energetic spacing of the quantized transverse-momentum subbands, which corresponds well with the energetic spacing determined from geometric considerations [14]. We evaluate the magnetic flux dependent surface state dispersion and identify clear anti-correlated conductance maxima and minima in the gate voltage dependent transconductance at full-integer $\Phi = i \cdot \Phi_0$ and half-integer $\Phi = (i + 1/2) \cdot \Phi_0$ values of the magnetic flux quantum applied coaxial to the nanoribbon. In the analysis of the gate voltage dependent occupation of these quantized states we use a spin degeneracy factor of $g_s = 1$ [18]. We find that the effective capacitance from this analysis compares well with the effective capacitance determined using our electrostatics model. Results therefore provide evidence for a magnetic-flux dependent topological phase transition in our narrow TI nanoribbons, which provides an odd number of surface-state band crossings at half-integer values of the magnetic flux quantum. This is an important requirement for the realization of gate-tunable Majorana devices that are partially covered by a superconducting metal [2]. The asymmetric chemical potential along the nanoribbon perimeter within such devices has just recently been reported to be advantageous for the detection of Majorana bound states [49]. We show that our selectively deposited TI nanoribbon devices can be used to fabricate highly-scalable and gate-tunable networks of quasi-1D TI nanoribbon structures, despite the presence of a high bulk background doping typically identified in these molecular beam epitaxy grown devices. Together with the realistic model for a TI band that includes both bulk components and inhomogeneous Fermi-level pinning on the surface, this opens up a whole new perspective in quantum technology, especially for circuits with network structures for Majorana experiments [6, 7, 50].

Acknowledgements

The authors would like to thank F. Lüpke for insightful discussions.

Author contributions D.R., J.K., E.Z. and A.R.J. have fabricated substrates for the selective area epitaxy in the cleanroom. A.R.J, G.M. and P.S. have performed the selective area epitaxy of the topological insulator thin film using molecular beam epitaxy. J.S. and S.K. have deposited the LaLuO₃ and HfO₂ dielectric layer using pulsed laser deposition and atomic layer deposition, respectively. D.R. has performed the electrical characterization of devices using a variable temperature insert cryostat. K.M. has performed the simulation of the relative gate potential and the modelling of the effective capacitance. The project has been supervised by and discussed with D.G., H.L., and Th.S.

A Appendix

To resolve the shift of the charge density locally on the nanoribbon perimeter, we solve the generalized Poisson equation for an inhomogeneous dielectric medium:

$$\nabla \cdot [\epsilon(\mathbf{r})\nabla V(\mathbf{r})] = 0. \quad (8)$$

The boundary conditions are given by $V(\mathbf{r}) = V_g$ at the surface of the metal gate, and $V(\mathbf{r}) = 0$ at the nanowire surface (assumed to be a perfect metal that completely screens the electric field in the interior with a shift of charge density on the surface). For the remaining (artificial) boundaries of the simulated region, we consider Neumann boundary conditions, $\mathbf{n} \cdot \nabla V(\mathbf{r}) = 0$ (corresponding to dielectric with $\epsilon \rightarrow +\infty$), with \mathbf{n} the unit vector normal to the boundary, keeping the value of the potential floating. At the interface between two insulating materials with different dielectric constants, the following relation holds:

$$\epsilon_1 \mathbf{n} \cdot \nabla V(\mathbf{r})|_1 = \epsilon_2 \mathbf{n} \cdot \nabla V(\mathbf{r})|_2, \quad (9)$$

with \mathbf{n} a unit vector normal to the interface and the subscript 1 or 2 denoting the different sides of the interface at which the dielectric constant and the gradient of the voltage profile are evaluated.

The induced (2D) charge density on the nanowire surface can be obtained from the following expression:

$$n(\mathbf{r}) = \frac{\epsilon(\mathbf{r})}{e} \mathbf{n} \cdot \nabla V, \quad (10)$$

with \mathbf{n} the unit vector normal to the nanowire surface this time around. This induced charge density can be related to the capacitance $C(\mathbf{r})$ (locally) through the relation: $C(\mathbf{r}) = en(\mathbf{r})/V_g$.
