Abstract

A shower array exploiting the full coverage approach with a high segmentation of the readout allow to image the front of atmospheric showers with unprecedented resolution and detail. The grid distance determines the energy threshold (small energy showers are lost in the gap between detectors) and the quality of the shower sampling. Therefore, this experimental solution is needed to detect showers with a threshold in the 100 GeV range. The full coverage approach has been exploited in the ARGO-YBJ experiment. In this contribution we will summarise the advantages of this technique and discuss possible applications in new wide field of view detectors.

1 Introduction

Gamma-ray astronomy above a few hundreds of GeV can be studied in a statistically significant way only with ground-based detectors exploiting the different components of Extensive Air Showers (EAS). The classical approach is to detect, with suitable telescopes, the Cherenkov radiation produced in atmosphere by secondary charged particles in air showers. Another possibility is to sample the charged particles at ground with arrays of detectors. The main characteristics and differences between air shower arrays and Imaging Atmospheric Cherenkov Telescopes (IACT) are summarised in the Table 1.

In shower arrays large areas (typically $10^4 - 10^5 \text{ m}^2$) are instrumented with charged particle detectors, usually scintillation counters, Resistive Plate Chambers (RPCs) or water Cherenkov tanks. The tail particles of the shower are sampled at a single depth (the observational level) and at fixed distances from the shower core position. The key observables in all air shower arrays are the local shower particle densities and the secondary particle arrival times with which to reconstruct the shower arrival direction, the energy and the kind of the primary

Table 1: Characteristics of air shower arrays and IACTs.

	Air Shower Array	IACT
Energy Threshold	Low (≈ 100 GeV)	Very low (≈ 10 GeV)
Max Energy	Very High ($\approx 10^{15}$ eV)	Limited (≈ 100 TeV)
Field of View	Very Large (≈ 2 sr)	Limited (≈ 5 deg)
Duty-cycle	Very large ($\approx 100\%$)	Very Small ($\approx 15\%$)
Energy Resolution	Modest ($\approx 100 - 20\%$)	Good ($\approx 15\%$)
Background rejection	Good ($> 80\%$)	Excellent ($> 99\%$)
Angular Resolution	Good ($\approx 1-0.2$ deg)	Excellent (≈ 0.05 deg)
Zenith Angle dependence	Very Strong ($\approx \cos\theta^{-(6-7)}$)	Small ($\approx \cos\theta^{-2.7}$)
Effective Area	Shrinks with zenith angle	Increase with zenith angle

particle. The resolutions of these measurements are limited by the large shower-to-shower fluctuations mainly due to the depth of the first interaction, which fluctuates by 1 radiation length (~ 37 g/cm²) for electromagnetic particles and by 1 interaction length (~ 90 g/cm²) for protons.

From an experimental point of view, the sampling of secondary particles at ground can be realized with two different approaches

1. Particle Counting. A measurement is carried out with thin ($\ll 1$ radiation length) counters providing a signal proportional to the number of charged particles (as an example, plastic scintillators or RPCs). The typical detection threshold is in the keV range.
2. Calorimetry. A signal proportional to the total incident energy of electromagnetic particles is collected by a thick (many radiation lengths) detector. An example is a detector constituted by many radiation lengths of water to exploit the Cherenkov emission of secondary shower particles. The Cherenkov threshold for electrons in water is 0.8 MeV and the light yield is ≈ 320 photons/cm or ≈ 160 photons/MeV emitted at 41° .

The mentioned experimental approaches have been applied in the last two decades in two different ground-based TeV survey instruments:

- (1) Water Cherenkov (Milagro) [1].
- (2) Resistive Plate Chambers (ARGO-YBJ) [2].

In both experiments the instrumented areas of the core detectors were similar, a large central water reservoir 60×80 m² for Milagro and a RPC carpet 74×78 m² for ARGO-YBJ. ARGO-YBJ was the first experiment to exploit the full coverage approach at extreme altitude. The Water Cherenkov approach was later used in the HAWC and LHAASO experiments. The RPC technology is widely used in particle physics experiments.

2 The ARGO-YBJ experiment

The ARGO-YBJ experiment, located at the Yangbajing Cosmic Ray Observatory (Tibet, PR China, 4300 m a.s.l., 606 g/cm²), is constituted by a central carpet $\sim 74 \times 78$ m², made of a single layer of Resistive Plate Chambers (RPCs) with $\sim 93\%$ of active area, enclosed by a guard ring partially instrumented ($\sim 20\%$) up to $\sim 100 \times 110$ m². The apparatus has a modular

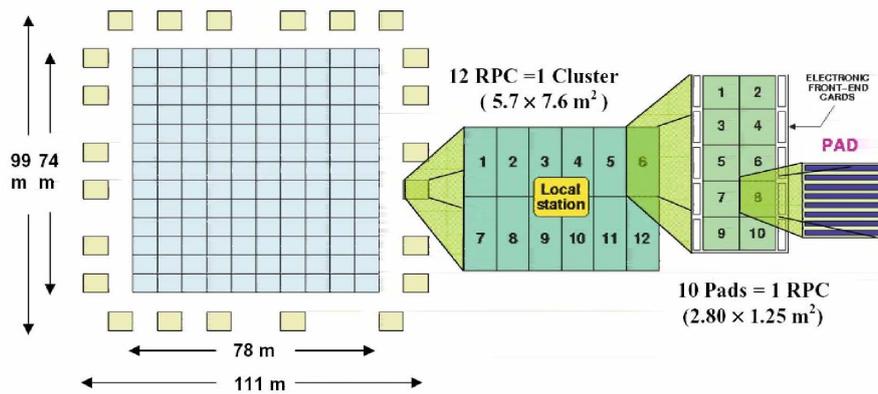

Figure 1: Layout of the ARGO-YBJ experiment [3] (see text for a description of the detector).

structure, the basic data acquisition element being a cluster ($5.7 \times 7.6 \text{ m}^2$), made of 12 RPCs ($2.85 \times 1.23 \text{ m}^2$ each). Each chamber is read by 80 external strips of $6.75 \times 61.80 \text{ cm}^2$ (the spatial pixels), logically organized in 10 independent pads of $55.6 \times 61.8 \text{ cm}^2$ which represent the time pixels of the detector [4]. The readout of 18,360 pads and 146,880 strips is the experimental output of the detector. In addition, in order to extend the dynamical range up to PeV energies, each chamber is equipped with two large size pads ($139 \times 123 \text{ cm}^2$) to collect the total charge developed by the particles hitting the detector [5]. The RPCs are operated in streamer mode by using a gas mixture (Ar 15%, Isobutane 10%, TetraFluoroEthane 75%) for high altitude operation [6]. The high voltage settled at 7.2 kV ensures an overall efficiency of about 96% [7]. The central carpet contains 130 clusters and the full detector is composed of 153 clusters for a total active surface of $\sim 6700 \text{ m}^2$ (Fig. 1). The total instrumented area is $\sim 11,000 \text{ m}^2$.

Because of the small pixel size, the detector is able to record events with a particle density exceeding $0.003 \text{ particles m}^{-2}$, keeping good linearity up to a core density of about 15 particles m^{-2} . This high granularity allows a complete and detailed three-dimensional reconstruction of the front of air showers at an energy threshold of a few hundred GeV, as can be appreciated in Fig. 2 (Left Plot) where a typical shower detected by ARGO-YBJ is shown. Showers induced by high energy primaries ($>100 \text{ TeV}$) are also imaged by the charge readout of the large size pads (see Fig. 2, Right Plot), which allow the study of shower core region with unprecedented resolution [5].

The median energy of the first multiplicity bin (20-40 fired pads) for photons with a Crab-like energy spectrum is $\sim 340 \text{ GeV}$ [8], with a $\approx 50\%$ efficiency in the detection of 100 GeV gamma-induced showers. The granularity of the read-out at centimeter level and a noise of accidental coincidences of 380 Hz/pad allowed to sample events with only 20 fired pads, out of 15,000, with a noise-free topological-based trigger logic.

The benefits in the use of RPCs in ARGO-YBJ are [2, 9]: (1) high efficiency detection of low energy showers by means of the high density sampling of the central carpet (the detection efficiency of 100 GeV photon-induced events is $\approx 50\%$ in the first multiplicity bin); (2) unprecedented wide energy range investigated by means of the digital/charge read-outs ($\sim 300 \text{ GeV} \rightarrow 10 \text{ PeV}$); (3) good angular resolution ($\sigma_\theta \approx 1.66^\circ$ at the threshold, without any lead layer on top of the RPCs) and unprecedented details in the core region by means of the high granularity of the different read-outs. RPCs allowed to study also charged CR physics (energy spectrum, elemental composition and anisotropy) up to about 10 PeV.

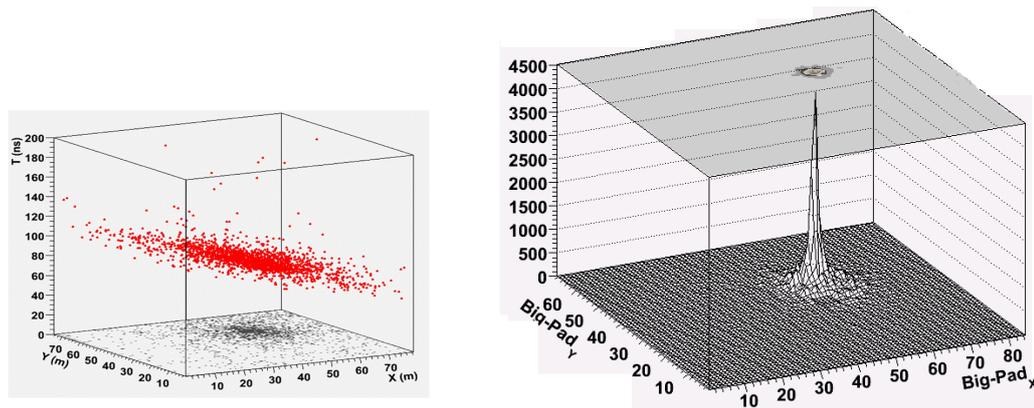

Figure 2: Showers imaged by the ARGO-YBJ central carpet with the digital (left plot: the space-time structure of a low energy shower provided by the strip/pad system) and the charge (right plot: the core of a high energy shower imaged by the charge read-out) read-outs [3].

2.1 The angular resolution

The direction of the primary particle is obtained after reconstructing the time profile of the shower front by using the information from each timing pixel of the experiment. Shower particles are concentrated in a front of a nearly spherical shape. A good approximation for particles not far from the shower core is represented by a cone-like shape with an average cone slope of about 0.10 ns/m. The accuracy in the reconstruction of the shower arrival direction mainly depends on the capability of measuring the relative arrival times of the shower particles.

The angular resolution of a shower array is a combination of the temporal resolution of the detector unit, the dimension of apparatus, i.e. the dimension of the lever arm in the fitting procedure of the shower front, and the number of temporal hits, i.e. the granularity of the sampling.

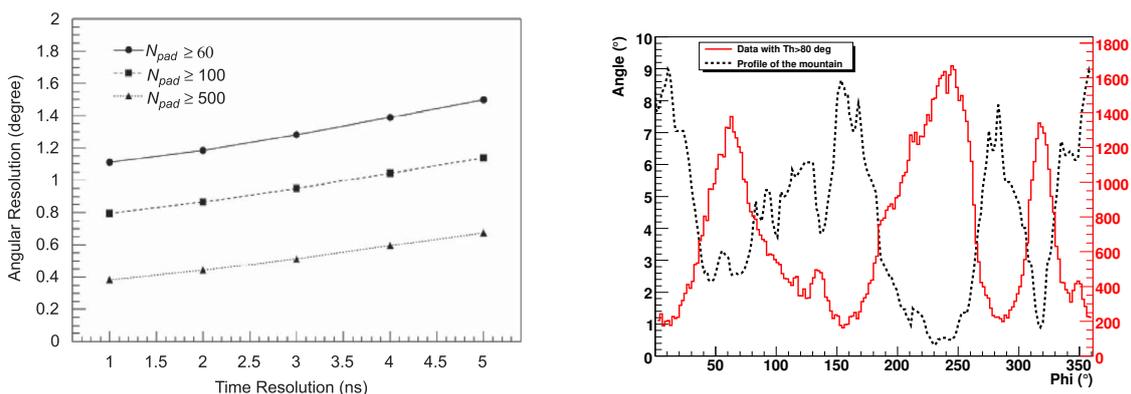

Figure 3: Left Panel: Angular resolution vs time resolutions for RPCs in the ARGO-YBJ experiment. Events with $N_{pad} \geq 60, 100$ and 500 fired pads have been selected [7]. Right Panel: Azimuthal distribution of showers arriving with a zenith angle > 80 deg compared with the mountain landscape around the detector.

The time resolution of each detector is determined by the intrinsic time resolution, the propagation time of the signal and the electronic time resolution. As an example, for the ARGO-YBJ experiment the total detector resolution is ≈ 1.3 ns (including RPC intrinsic jitter,

strip length, electronics time resolution) [9]. The dependence of the angular resolution on the time resolution of RPCs in the ARGO-YBJ experiment is shown in the Left Panel of Fig. 3 [7]. Events with $N_{pad} \geq 60$, 100 and 500 fired pads on the central carpet have been selected. As it can be seen from the figure, a time resolution in the range between 1 and 2 ns corresponds to a very small change in the angular resolution because the time jitter of the earliest particles in high multiplicity events (>100 hits) is estimated ≈ 1 ns [10, 11].

The ARGO-YBJ capability in reconstructing the shower direction is showed in Right Panel of Fig. 3 where the azimuthal distribution of showers arriving with a zenith angle > 80 deg is compared with the mountain landscape around the detector. As it can be seen, an impressive strong anti-correlation between shower flux and mountains is clearly evident, even for narrow valleys between the mountains. We emphasize that no lead layer to improve the angular resolution by converting secondary photons and absorbing delayed electrons is added on top of RPCs. Therefore, this plot shows the shower direction reconstruction capability of RPCs alone.

3 Cosmic Ray background rejection from ground

In 1960 Maze and Zawadzki [12] suggested that in gamma-ray astronomy with shower arrays the background of CRs can be identified and rejected by identifying EAS with an abnormally small number of muons N_μ , the so-called ‘muon poor’ technique. The existence of such ‘unusual’ showers is due to the relatively small photo-nuclear cross section compared with the corresponding value for the proton-nucleus and nucleus-nucleus cross-sections. In gamma showers muons are produced mainly by the photo-production of hadrons $\gamma + \text{air} \rightarrow n\pi^\pm + m\pi^0 + X$ ($\sigma_{\gamma\text{-air}} \sim 1\text{-}2$ mb), followed by the pion decays in muons and photons, and by muon pair production ($\sigma_{\gamma\text{-air}} \sim 12$ μb).

The efficacy of background rejection exploiting the muon content is limited by the number of muons that can be detected. According to MonteCarlo simulations, in a proton-induced shower the number of muons is approximately proportional to the energy of the primary, with about 20 muons above 1 GeV for a 1 TeV proton (200 muons for a 10 TeV muon), but only 4 muons within 150 m of the shower core. As a consequence, the muon poor technique is effective above a few TeV.

In addition, the fluctuations in the muon number (for a fixed proton energy) are larger than Poisson, with a Gaussian width of $\approx 2.5\sqrt{N_\mu}$, thus there are more events with zero muons than a Poisson calculation. This is an important limiting factor for background discrimination at low energy. Another limiting factor is the high rate of single muons unassociated to showers at ground. The need for *large full coverage muon detector* is evident to exploit the muon poor technique starting from the TeV energy range.

The background-free regime is very important because in this case the sensitivity is the inverse of the effective area of the array multiplied by the time spent observing a source. Thus, an EAS array with a comparable effective area to a IACT array, with more than one order of magnitude larger time on source, will have a much better sensitivity to highest energy sources.

ARGO-YBJ was not able to discriminate muons, anyway, we note that in the Milagro and ARGO-YBJ experiments the limited capability to discriminate the background was mainly due to the small dimensions of the central detectors (pond and carpet). In fact, in the new experiments HAWC [13] and LHAASO [14, 15], the discrimination of the CR background is made studying shower characteristics far from the shower core (at distances $R > 40$ m from the core position, the dimension of the Milagro pond and ARGO-YBJ carpet).

4 What's next? STACEX in the Southern Hemisphere

The recent results obtained by the LHAASO Collaboration with half detector in data taking revealed the existence of a large number of gamma-ray sources emitting photons with energies well beyond 500 TeV [15]. The unexpected observation of these sources in the Northern hemisphere suggests the opportunity to discover tens of similar Ultra High Energy emissions in the Inner Galaxy by a detector able to detect PeV photons located in the Southern hemisphere.

An ideal observatory for PeVatrons

- should be able to perform an unbiased survey to search for different and possibly unexpected classes of sources;
- should have a dynamical range from 100 GeV to 10 PeV to measure the energy spectra with the same detector;
- should have an effective area bigger than 0.5 km^2 to collect adequate photon statistics;
- should have a very good energy resolution (20% or better) above a few tens of TeV to test spectral break and cutoffs;
- should have a good angular resolution ($\sim 0.2^\circ$) to resolve sources which might be hidden in the tails of bright sources and compare and correlate with gas surveys;
- should have a background discrimination capability at a level of 10^{-4} - 10^{-5} starting from a few tens of TeV.

The proposed STACEX (Southern TeV Astrophysics and Cosmic rays EXperiment) detector (see Fig. 4) [16] consists of a full coverage core detector, located at 5000 m asl, constituted by

- (a) a $150 \times 150 \text{ m}^2$ RPC full coverage carpet, with a 0.5 mm lead layer on top;
- (b) a dense muon detector array below the carpet constituted by water Cherenkov tanks buried under 2.5 m of soil;

Adequate photon statistics above 50 TeV is provided by an array of 1 m^2 plastic scintillators and muon detectors in a 30 m grid around the core detector covering a total area of 0.5 km^2 at least.

This layout is motivated by following reasons

- (1) dense sampling by the RPC carpet for a very low energy threshold ($\sim 100 \text{ GeV}$);
- (2) wide energy range, $100 \text{ GeV} \rightarrow 10 \text{ PeV}$;
- (3) high granularity of the carpet read-out to have an energy resolution $< 20\%$ above 10 TeV and to have a very good angular resolution ($\sim 0.2^\circ$ above 10 TeV);
- (4) high efficiency rejection of the CR background by the muon-poor technique. With a continuous $22,500 \text{ m}^2$ muon detector below the RPC carpet the background-free detection of gamma-rays is expected to start from a few tens TeV;
- (5) measurement of the elemental composition with two different independent observables, shower core characteristics (in a ARGO-like measurement [2]) and muon component.

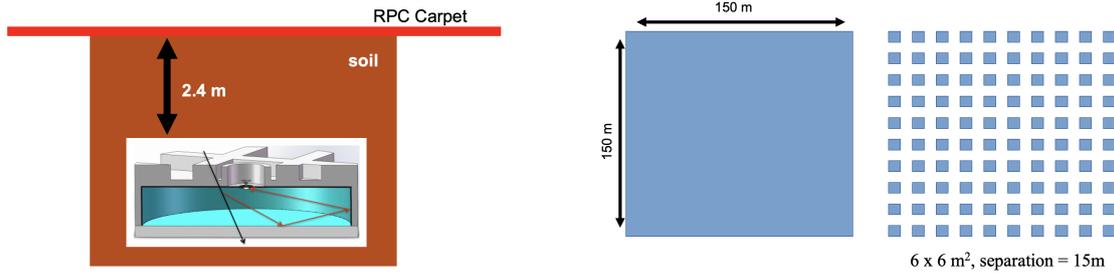

Figure 4: Left Panel: STACEX layout. Right Panel: Layouts of 2 different muon detectors under the RPC carpet.

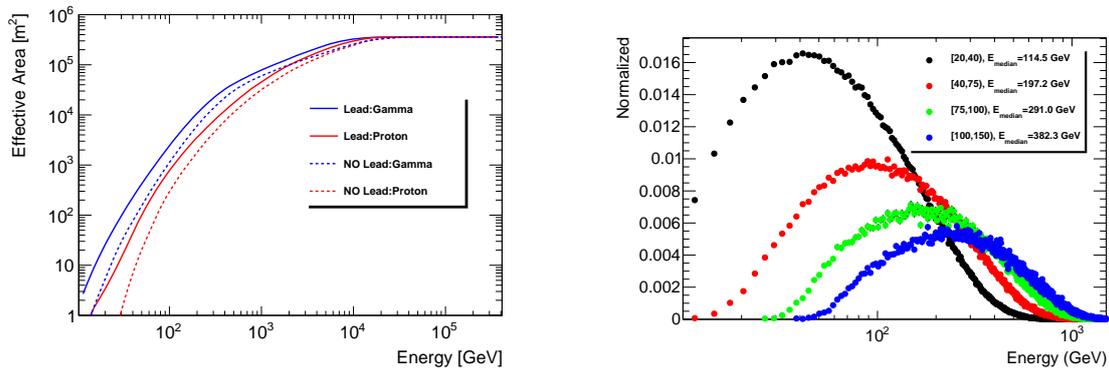

Figure 5: Left Panel: STACEX effective areas for photon- and proton-induced showers as a function of the primary energy. Right Panel: Energy distributions of photon-induced showers for 4 different strip multiplicities measured by the RPC carpet [16].

Results of preliminary calculations are shown in the following [16]. The effective area for showers produced by primary photons and protons are shown in the Left Panel of Fig. 5 as a function of the median energy for different bins of strips multiplicity. As you can see from the figure, we have $A_{\text{eff}} \sim 3 \times 10^3 \text{ m}^2$ at 100 GeV and $A_{\text{eff}} \sim 10^6 \text{ m}^2$ at 100 TeV. The energy distributions are shown in the Right Panel of Fig. 5 for 4 different strip multiplicities. The peak energy of the first bin is about 100 GeV. The energy resolution is about 50% at the threshold.

In the Left Panel of Fig. 6 the angular resolution σ_θ (the angle containing the 72% of the events) is shown. We have $\sigma_\theta \sim 0.5^\circ$ at 1 TeV and $\sigma_\theta \sim 0.25^\circ$ at 10 TeV. The core resolution for gamma-ray events is shown in the Right Panel of Figure 6 as a function of the reconstructed energy. The resolution is about 20 m at 100 GeV and $\sim 2 \text{ m}$ at 100 TeV.

4.1 Full coverage detection of muons

The lateral distribution of muons is much wider than electromagnetic particles and their number much lower. Therefore, the detection of muons can be affected by large sampling fluctuations. Detection of muons with a full coverage approach can lower the fluctuations and allow a background-free measurement in UHE gamma-ray astronomy starting from a few tens of TeV.

To evaluate the background discrimination capability of the proposed array we simulated 2 different water Cherenkov muon detector layouts: (1) a continuous muon detector below the RPC carpet with a total area of 22,500 m²; (2) a 10×10 array of water tanks with a total area of 3,600 m². In both cases the detectors, made by 1.5 m of water with downward PMTs, are buried under 2.5 m of soil to reduce the punch-through probability by high energy electromagnetic particles. As a consequence, the muon energy threshold is about 1 GeV. To

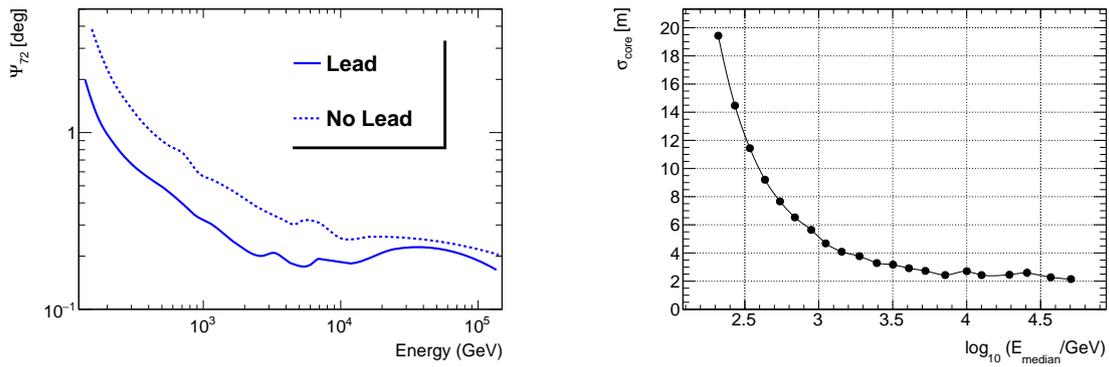

Figure 6: Left Panel: Angular resolution for photon-induced showers as a function of the primary energy. Right Panel: Shower core resolution for photon-induced showers as a function of the primary energy [16].

further reduce the contamination in the analysis we excluded the muon detectors inside a circular area with 20 m radius around the reconstructed shower core position.

In the Left Panel of Figure 7 the number of muons detected by a $150 \times 150 \text{ m}^2$ continuous muon detector for proton- and photon-induced showers is shown as a function of the strip multiplicity. We reject the CR background according to a selection cut removing showers with a muon content bigger than a value determined to optimize the sensitivity as a function of the multiplicity. The fraction of the photons and protons surviving a selection cut determined using a binary classification method with a logistic function as a function of the primary photon energy is shown in the Middle Panel of Figure 7. For energies above 100 TeV we reject the proton background at a level of $3 \cdot 10^{-4}$ with nearly 100% of photons surviving. The so-called ‘Q-factor’ parameter is shown in the Right Panel as a function of the primary energy for the 2 investigated muon detector layouts. Calculations are still preliminary but these results show that with a full coverage measurement of muons the background-free regime could start at a few tens of TeV.

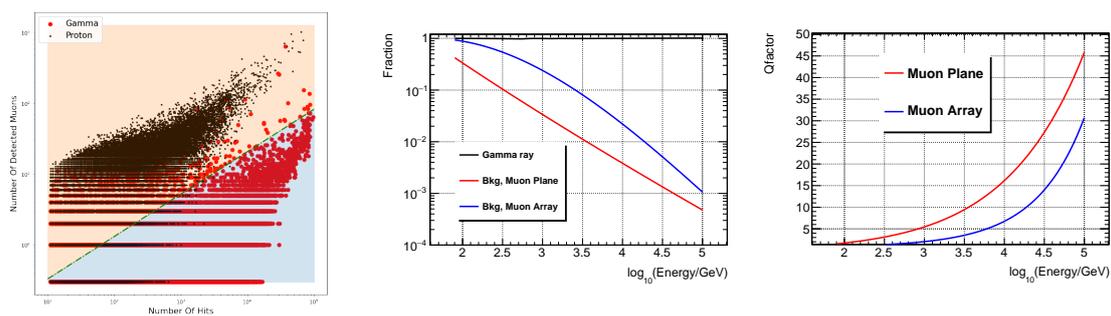

Figure 7: Left panel: Number of muons detected by a $150 \times 150 \text{ m}^2$ continuous muon detector for proton and photon induced showers as a function of the strip multiplicity. Middle panel: The survival fraction of gamma-ray and cosmic ray background events as a function of the energy. Right panel: Q-factor parameter as a function of the photon primary energy for the 2 investigated muon detector layouts [16].

In Fig. 8 the sensitivity of the STACEX central detector, located at 5000 m asl [16], is compared to that of LHAASO at 4400 m asl [14] and SWGO at 5000 m asl [17].

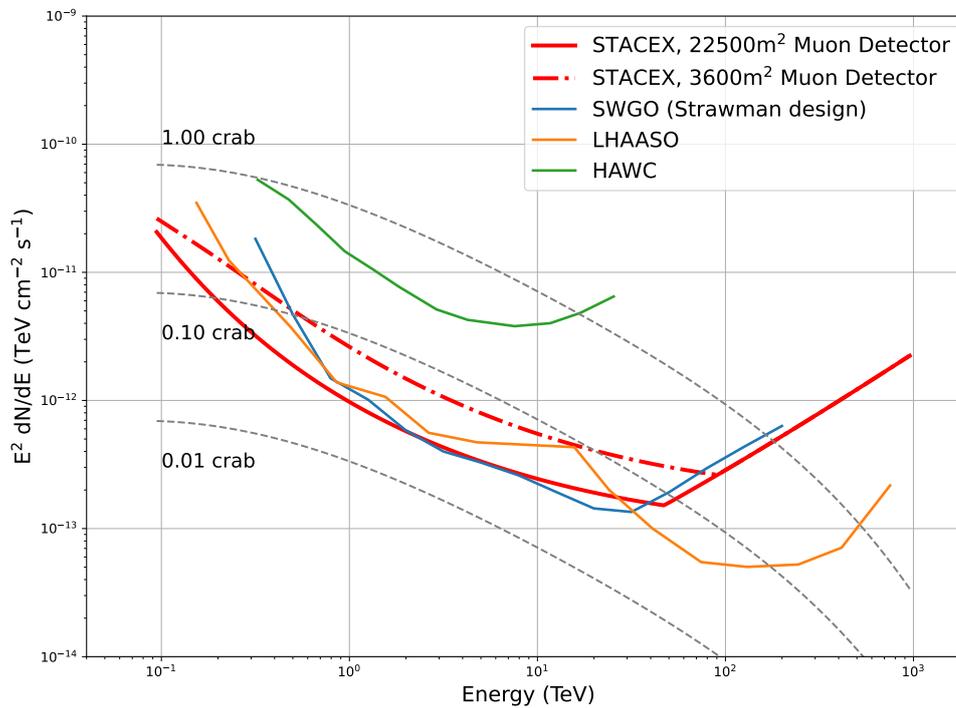

Figure 8: Differential sensitivity of STACEX central detector in 1 year compared to HAWC (22,500 m² at 4100 m asl) [13], LHAASO (1.3 km² at 4400 m asl) [14] and SWGO (220,000 m² at 5000 m asl) [17]. The calculations refer to the 2 different muon detector layouts discussed in the text. The effect of a shower array located around the STACEX central carpet is not included yet [16].

As you can see, a smaller full coverage detector has a sensitivity comparable with much larger arrays like LHAASO or SWGO. The main reason is the full coverage layout of the muon detector allowing to efficiently reject charged cosmic ray background in the TeV range and to have a background-free regime starting from about 50 TeV. We remind that in LHAASO the large area muon detector consists in a sparse array (coverage $\approx 4.4 \times 10^{-2}$) with an energy threshold of about 10 TeV. In addition the full coverage of the RPC carpet allows a very low energy threshold. The effect of a shower array located around the central carpet is not included yet.

5 Conclusion

Detection of EAS with a full coverage detector is the right solution to lower the energy threshold in the 100 GeV range, to study the characteristics of showers with unprecedented details and to discriminate the background of charged CRs working in a background-free regime starting from a few tens of TeV.

ARGO-YBJ exploited this approach operating for the first time a full coverage carpet at 4300 m asl showing that bakelite-based RPCs can be safely operated at extreme altitudes for many years providing: (1) high efficiency detection of low energy showers (energy threshold

~ 100 GeV) by means of the dense sampling of the full coverage carpet; (2) unprecedented wide energy range investigated by means of the digital/charge read-outs (~ 100 GeV \rightarrow 10 PeV); (3) good energy and angular resolutions with unprecedented details in the shower core region by means of the high granularity of the read-outs.

Coupled with a full coverage muon detector this apparatus should be able to detect photons in a background-free regime starting from a few tens of TeV.
